20 Abstract

Accurate quantification of effect sizes has the power to motivate theory, and reduce 21 misinvestment of scientific resources by informing power calculations during study planning. 22 However, a combination of publication bias and small sample sizes ($\sim N = 25$) hampers 23 certainty in current effect size estimates. We sought to determine the extent to which sample sizes may produce error in effect size estimates for four commonly used paradigms assessing 25 attention, executive function and implicit learning (Attentional Blink (AB), Multitasking (MT), Contextual Cueing (CC), Serial Response Task (SRT)). We combined a large data-set 27 with a bootstrapping approach to simulate 1000 experiments across a range of N (13-313). Beyond quantifying the effect size and statistical power that can be anticipated for each study design, we demonstrate that experiments with lower values of N can potentially double or triple information loss. Furthermore, we identify the probability that sampling a similar 31 study will provide a reasonable effect size estimate, and show that using such an approach 32 for power calculations will lead to an imprecise estimate between 40-67% of the time, given 33 commonly used sample sizes. We conclude with practical recommendations for researchers 34 and demonstrate how our simulation approach can yield theoretical insights that are not 35 readily achieved by other methods; such as identifying the information gained from rejecting the null hypothesis, and quantifying the contribution of individual variation to error in effect 37 size estimates.

Introduction

39

Despite the complexity involved in disentangling the processes that underpin cognition,
decision making regarding experimental outcomes is often made on binary (i.e. pass or fail)
terms, across the psychological, neuroscientific and biomedical sciences (Szucs & Ioannidis,
2017). Theoretical predictions are often specified in terms of the presence or absence of a
given effect, and a yes/no decision is made about whether the null hypothesis (usually a
hypothesis of null differences) can be rejected. It seems unlikely that such binary
decision-making will be sufficient to disentangle the myriad functional systems that
comprises the brain's processes. An alternate approach is to develop theory and models that
predict the magnitude of the effect. Such magnitudes are often characterised as an effect size:
a standardised measure that reflects the extent to which an effect, such as a mean difference
between two conditions, is expected to generalise to the population (Cohen, 1988).

A prediction of effect magnitude is easier to disprove than a binary outcome, and 51 therefore constitutes a more desirable prediction for theory testing (Popper, 1959). To move towards theories that predict changes in effect size magnitude, it is helpful to gain an 53 understanding of how much insight is yielded from our current effect size estimates; i.e. how well are we currently quantifying effect sizes, and should we increase sample sizes to quantify them better? Indeed, recent work suggests that insufficiently powered studies are at increased risk of producing effect size estimates that are either inflated in magnitude, or are 57 in the incorrect direction (Chen et al., 2019; Gelman & Carlin, 2014). Here we seek to address how well we currently characterise effect sizes in the study of cognition, using some established paradigms in the fields of attention, executive function and implicit learning; namely the Attentional Blink (AB, Raymond, Shapiro, & Arnell, 1992), Multitasking (MT, Schumacher et al., 2001), Serial Response Task (SRT, Nissen & Bullemer, 1987), and Contextual Cueing (CC, Chun & Jiang, 1998) paradigms.

Accurate quantification of effect sizes is also desirable for study planning, as effect sizes

form the foundation of a priori power calculations (Cohen 1988). Here the researcher
determines the sample size (N) required to achieve sufficient power to correctly reject the
null hypothesis. The importance - and difficulty - of accurately determining the anticipated
effect size has been considered extensively elsewhere (Cohen, 1988; Gelman & Carlin, 2014;
Albers & Lakens, 2018; Cumming, 2014;, Egger, Smith, Schneider, & Minder, 1997; Guo,
Logan, Glueck, & Muller, 2013; Lakens, 2013; Szucs & Ioannidis, 2017; Westfall, Kenny, &
Judd, 2014). Standard approaches of determining an anticipated effect size involve
consulting a meta-analysis, basing effect-size estimates on a few similar studies (incomplete
sampling), or determining the smallest effect that is of theoretical relevance (e.g. Gelman &
Carlin, 2014). What remains somewhat less considered is the utility of knowing how effect
size estimates may vary across replications of an experiment (e.g. Cumming, 2014;
Lorca-Puls et al., 2018), i.e. what are the distributional properties of the effect size, given a
field that uses a comparable N across experiments?

The answer to this question can facilitate both study planning and theory development. 78 A paradigm that elicits a small effect that manifests with low variability across replications may be considered a more desirable target for theory and model development than a 80 paradigm that produces the same mean effect size but with wider variability. With regard to 81 study planning, identifying the lower bound of an expected effect size facilitates computation of the N required to achieve sufficient statistical power under the worst case scenario (Gelman & Carlin, 2014). Understanding how effect sizes vary across replications with a given N also allows computation of the likelihood that any single study has produced a 85 reasonably accurate estimate, which can inform the researcher who may be computing anticipated effect sizes on the basis of one or a few similar studies. There is also utility in knowing to what extent variability in effect size observations reduces when larger N are used instead. There may be an upper bound on the accuracy with which a particular effect can be estimated, for example, when the construction of a paradigm introduces a certain level of noise or measurement error that is larger than variation at the level of the individual.

Consequently, there may be a point of diminishing returns, where the cost of recruiting extra N will outweigh the gains in accuracy of effect size estimation.

Quantifying the range of effect sizes that may be observed across experimental 94 replications is not trivial. Indeed, it has been noted that the largest challenge in 95 experimental design is the prior identification of a plausible range of effect sizes (Gelman & Carlin, 2014). Meta-analytic and incomplete sampling approaches for determining an expected effect size are hampered by the quality of the existing literature (Brand, Bradley, Best, & Stoica, 2008; Friston, 2012; Gelman & Carlin, 2014; Lane & Dunlap, 1978; Lorca-Puls et al., 2018). A recent survey of 900 effect sizes across psychology disciplines 100 showed that effects from non-pre-registered studies were much larger than pre-registered 101 studies (r = 0.36 vs 0.16, Schäfer and Schwarz (2019)) suggesting that prior to 102 pre-registration, under-powered studies were contributing inflated effect size estimates to the 103 psychology literature. It is also difficult to determine, on the basis of existing literature, how 104 conclusions about effect sizes would differ if a given field of study was different, e.g. how 105 much published literature is likely to be missing if a larger N was used as standard? 106 Simulation studies offer the opportunity to ask how well a field is currently quantifying 107 effect sizes, and how a field's estimate of an effect size would change with differing levels of 108 statistical power. Typically, simulation studies generate data under some simplifying 109 assumptions about the data generation process (e.g. Albers & Lakens, 2018; Hedges, 1982; 110 Lane & Dunlap, 1978; Troncoso Skidmore & Thompson, 2013; Westfall et al., 2014). 111 Although this work is necessary for informing how effect size estimates behave under varying 112 conditions where ground truth is known, it is challenging to anticipate all the complexities of data from the repeated-measures designs used across a range of phenomena and processes, such as in the study of attention, executive function and implicit learning. Such data are often not normally distributed and carry varying levels of covariance between conditions. 116 Thus, there remains a question mark over the extent to which the results from simulation 117 work generalizes to real-world data. An alternative method is to simulate experimental 118

outcomes by bootstrapping smaller samples from larger, real data-sets (e.g. Lorca-Puls et al., 2018). This approach offers the opportunity to characterize the distributional qualities of effect sizes estimated from high-dimensional data-sets, using varying levels of N, while maintaining ecological validity.

In the current study, we applied such a simulation approach to characterize effect size 123 distributions yielded from the study of cognition. Participants (N=313) completed a 124 battery of cognitive tasks (AB, MT, SRT and CC) originally assembled to test the 125 relationship between attention, executive function and implicit learning. For each paradigm, 126 we simulated 1000 bootstrapped experiments across 20 Ns ranging from 13 to 313. For each 127 paradigm and from each set of simulations, we determined the impact of N on error in effect 128 size estimates. We asked how much variability of effect size estimates changes as a function 129 of N, and sought to identify a point at which increasing N may offer lower gains for 130 improving effect size estimates. We next determined how likely it is that a study will 131 produce an effect size estimate with sufficiently low error, as a function of N. We also sought 132 to determine the impact of N on the potential for missing literature for each paradigm, given 133 the case of publication bias. Last, we leveraged our dataset to identify features that 134 predicted error in effect size estimates, beyond the mean and standard deviation measures of 135 which they are comprised. We focused on higher order moments of inter- and intra-subject variability, as such measures remain undiscussed in simulation studies that assume normality, 137 yet can bias mean and variance estimates when datasets violate normality assumptions. The 138 results motivate guidelines for study design and interpretation, not only for future AB, MT, 139 SRT and CC studies, but also more broadly for the investigation of cognition.

141 Methods

2 Participants

The current study used a data set collected for a different pre-registered project examining the relationship between executive function and implicit learning. This data set contains performance measures from N=313 participants. Participants were undergraduate students, aged 18 to 35 years old (mean = 20.14 yrs, sd = 3.46). Of the total sample, 208 reported being female, and 269 reported being right handed. Participants received course credits as compensation. All procedures were approved by The University of Queensland Human Research Ethics Committee and adhered to the National Statement on Ethical Conduct in Human Research.

151 Apparatus

Experimental procedures were run on an Apple Mac Minicomputer (OS X Late 2014, 2.8 GHz Intel Core i5) with custom code using the Psychophysics toolbox (v3.0.14)

(Brainard, 1997; Pelli, 1997) in Matlab v2015b. Participants completed 7 tasks; Attentional Blink (AB), Multitasking (MT), Contextual Cueing (CC), Serial Response Task (SRT),

Visual Statistical Learning (VSL), Operation Span task and a Stop Signal Inhibition task.

Only the data from the AB, MT, CC and SRT are reported here. We opted not to report the VSL, OSPAN or Stop Signal data as their design did not lend themselves to the computation of a standardised effect size.

160 Procedures

Across all tasks, participants sat approximately 57 cm from the monitor. An overview of the task procedures is presented in Figure 1. Details regarding each of the task protocols are presented within each section below.

Attentional Blink (AB). The AB task taps limitations in the deployment of visual information processing over time. Participants are instructed to detect two targets from a rapidly presented series of visual items. Accuracy for the second target is poorer if it appears closer in time to the first target (at early lags, from lag 2 onwards), relative to further apart in time (Raymond et al., 1992).

Protocol.The AB protocol was the same as that reported in Bender et al (2016). 169 Each trial began with a black fixation cross in the center of a gray screen [RGB: 128, 128, 170 128 for a variable interval of 200-600 ms. On each trial, letter targets and digit distractors 171 were presented centrally for 100 ms in rapid serial presentation. The eight distractors were 172 drawn without replacement from the digits 2-9. The target letters were randomly selected 173 from the English alphabet, excluding I, L, O, Q, U, V and X. The first target (T1) was 174 presented third in the series (serial position 3), and T2 was presented at either lag 2 (200 175 ms), 3 (300 ms), 5 (500 ms) or 7 (700 ms) relative to T1. All stimuli subtended 1.72 x 2.31 $^{\circ}$ 176 (w x h) visual angle. Participants were instructed to make an unspeeded report of the 177 identity of both targets at the end of each trial. Participants completed 24 practice trials 178 and four test blocks of 24 trials. For the current analysis we calculated T2 accuracy, given that T1 was correctly reported (T2|T1), for each lag. 180

Multitasking (MT). MT paradigms tap the performance costs incurred when individuals attempt to perform more than one task concurrently. Participants are instructed to complete two simple sensorimotor tasks as accurately and quickly as possible under single or multitask conditions. RTs to the constituent tasks are typically slowed for multitask relative to single task conditions (see Pashler (1994), for a review).

Protocol. The MT protocol was previously reported in Bender et al (2016). Each trial began with a black fixation cross presented in the center of a gray screen [RGB: 128, 128, 128] for a variable interval of 200-600 ms. Next either one of two coloured circles [red, RGB: 237, 32, 36 or blue, RGB: 44, 71, 151] or one of two sounds (complex tones taken from Dux, Ivanoff, Asplund, & Marois, (2006)), or both (circle and sound) were presented for 200

ms. The coloured circle subtended 1.3° visual angle. Participants were instructed to respond 191 to all tasks as quickly and accurately as possible, by using the appropriate key presses 'A' or 192 'S' for left hand responses, 'J' or 'K' for right hand responses, with the task-hand mapping 193 counterbalanced across participants. The MT protocol consisted of 4 blocks of 36 trials, 194 with each trial type (single-task [ST] visual, ST auditory or MT) randomly mixed within 195 blocks. Participants completed the MT protocols after completing two ST blocks as practice, 196 one for the visual task and one for the auditory task. We analysed mean response times 197 (RTs) to each task x modality condition. 198

Serial Response Task (SRT). The SRT paradigm taps sensorimotor sequence 199 learning; specifically the extent to which individuals speed up responses when cue stimuli 200 follow a predictable sequence, relative to when cue stimuli are presented randomly (Nissen & 201 Bullemer, 1987). As participants receive no explicit instructions or cues regarding the 202 sequence, it has been assumed that the SRT taps implicit sequence learning (Nissen & 203 Bullemer, 1987), although the extent to which performance gains reflect implicit or explicit 204 learning mechanisms continues to be debated (Clegg, DiGirolamo, & Keele, 1998; Goschke, 205 1998). Participants are instructed to make a button press response to one of four spatially 206 compatible target stimuli as quickly and accurately as possible. Unknown to the participants, the presentation of the target stimuli will on occasions follow a repeating rather than a random sequence. 209

Protocol. The SRT was adapted from Nissen & Bullemer (1987). Four square
placeholders were presented across the horizontal meridian. A red circle [RGB: 255, 0, 0]
appeared in one of the 4 squares for 500 ms. This served as the target stimulus. Participants
responded by pressing the finger of their dominant hand that spatially aligned to the target
circle, using the relevant 'j', 'k', 'l' or ';' keys. The subsequent target stimulus appeared 500
ms after a correct response had been made. Participants completed 4 blocks of 100 trials.
For blocks 1 and 4, the location of the target stimulus for each trial was randomly selected
from a uniform distribution. These blocks are referred to as 'Random'. For blocks 2 and 3, a

repeating sequence of 10 elements was used to determine the target location. The sequence
was repeated 10 times. The repeating sequence was 4-2-3-1-3-2-4-2-3-1, with 1 being the
leftmost placeholder, and 4 being the rightmost placeholder. These blocks are referred to as
'Sequence' blocks. Learning in the SRT is tested by comparing mean RTs between Sequence
and Repeat blocks in the latter half of the experiment (block 4 vs 3).

Contextual Cueing (CC). CC tasks tap how the visual system exploits statistical 223 regularities to guide visual search (Sisk, Remington and Jiang, (2019); Jiang and Sisk 224 (2020)). Participants are typically asked to report the orientation of a rotated 'T' target 225 presented among an array of distractor 'L's. Participants are not informed that a set of the 226 displays are repeated throughout the course of the experiment, while the remaining displays 227 are novel to each trial. Typically RTs to the repeat displays become faster than novel 228 displays throughout the course of the experiment (e.g. Chun & Jiang, 1998; Nydam, Sewell, 229 & Dux, 2018). Participants are typically poor at recognising repeat displays in a subsequent 230 recognition test (Sisk, Remington and Jiang, (2019); Jiang and Sisk (2020)), which has 231 prompted the conclusion that CC reflects a process of implicit learning (but see Vadillo, 232 Konstantinidis, & Shanks, 2016; Vadillo, Linssen, Orgaz, Parsons, & Shanks, 2020; Vadillo, 233 Malejka, Lee, Dienes, & Shanks, 2021).

The CC protocol was the same as that reported by Nydam et al (2018) 235 which is modeled on Chun and Jiang (1998). Each trial began with a white fixation cross 236 presented on a grey screen [RGB: 80, 80, 80]. An array of 12 L's and a single T were then 237 presented presented within an invisible 15 x 15 grid that subtended 10° x 10° of visual angle. 238 Orientation of each L was determined randomly to be rotated 0°, 90°, 180° or 270° clockwise. 239 The T was oriented to either 90° or 270°. Participants reported whether the T was oriented 240 to the left (using the 'z' key) or the right (using the 'm' key), as quickly and accurately as possible. The task consisted of 12 blocks of 24 trials. For half the trials in each block, the display was taken (without replacement) from 1 of 12 configurations that was uniquely 243 generated for each participant, where the location of the distractors and target (but not the

orientation of the target) was fixed. These trials were called 'repeats'. For the remaining 245 trials, the display was randomly generated for each trial, making them 'novel'. Displays were 246 generated with the constraint that equal items be placed in each quadrant and each 247 eccentricity. Target positions were matched between the repeat and novel displays for both 248 quadrant and eccentricity. The exact location of the item was jittered within each cell for 249 each presentation, to prevent perceptual learning or adaptation to the specific position of the 250 item. The order of display type (repeat vs novel), configuration (1:12) and target orientation 251 (left or right) was randomised for each block. Mean RTs to each block (1:12) and display 252 type (repeat vs novel) were taken as the dependent variable. 253

254 Statistical Approach

All the data and code used for the current analyses are available online. All data were analysed using R-Team (2015) and RStudio (RStudio Team, 2020). The analysis of the data from each task followed two steps; first, to ascertain that we observed the typical findings for each of the paradigms, we applied the relevant conventional statistical model to the full dataset (N=313). Next, we implemented a simulation procedure to determine the effect sizes and p-values that would be attained over many experiments conducted at multiple levels of sample size.

Simulation procedure. For each paradigm, we simulated experiments across 20 262 different sample sizes (N), defined on a logarithmic interval between N_{13} and N_{313} (N = [13,263 15, 18, 21, 25, 30, 36, 42, 50, 59, 69, 82, 97, 115, 136, 160, 189, 224, 265, 313). We opted for 264 a logarithmic interval given that changes in effect size variability should be greater across changes of N when N is lower, relative to when Ns are higher. To simulate k=1000experiments at each of our chosen N, we sampled N participants from N_{max} (N₃₁₃) over k 267 iterations. The relevant analysis was applied to each of the samples. Details regarding which 268 analyses were applied to each k sample are listed below for each paradigm. Sampling with 269 replacement ensured that the samples carried the Markov property. One potential concern is 270

that any reductions in observed effect size variability may be attributable to saturation as 271 the simulated N approaches the maximum (N_{313}) , rather than a genuine reduction in 272 variance of the estimate of the effect. Specifically, it could be that as N approaches 313, the 273 overlap of participants between samples is greater than when N equals a lower number such 274 as 13. It follows then that any decreasing variability in effect size estimates at higher $N_{\rm S}$ 275 could be due to the decrease in variability of the samples, rather than the improved estimate 276 of the population variance that should come with a larger N. We have run simulations that 277 argue against this explanation (see appendix i). 278

Effect Sizes. For each paradigm, we report the following information from the simulated effect size distributions; first we used simulations using N_{313} to provide a best estimate of the effect size distribution. We therefore report, for each paradigm, the mean (Mdn), median (Mdn): when different to the M), standard deviation (SD), the .025 (lower bound, (LB)) and .975 (upper bound, (LB)) quantiles. These values can be used to define, (LB)) are (LB)0 priori, the range of anticipated effect sizes for future experiments, and consequently, can be used to inform study design.

We next determined to what extent using an N that is typical for the field impacts the effect size distribution. We report the same summary statistics as above, from the simulation using the N that is closest to the typical N for that task (N_{med}) . To identify the typical N, we conducted a survey of the recent literature and computed the median N for each paradigm (see below). We next computed the precision loss incurred from using N_{med} by taking the ratio of the difference between the LB and UB quantiles for N_{med} and N_{313} :

$$qq\text{-}ratio = \frac{UB_{N_{med}} - LB_{N_{med}}}{UB_{N_{313}} - LB_{N_{313}}}$$

We refer to this measure from now as the qq-ratio. The qq-ratio indicates how underor over-inflated effect size estimates may be - a qq-ratio of 2 would suggest that effect sizes may be twice as low or high as the LB or UB of the best estimate. For each task, we also report the largest observed qq-ratio and the N for which the qq-ratio reaches less than double. Note that although we expect qq-ratios to decrease as some function of $\frac{1}{N}$ (given that variance depends on this term), the exact relationship between N and precision loss will be dependent on population variance and measurement error for any given paradigm. We also present qq-ratios across all N's, to provide an idea of potential precision gains from increasing sample size.

Next we computed estimates regarding the extent to which precision loss in effect size 301 estimates may lead a researcher awry during study planning. To determine how often 302 sampling one or two similar studies with N_{med} may induce biases in power calculations, we 303 computed for each task and N, the proportion of simulated observations that fell within the 304 LB and UB quantiles of the best estimate (N_{313}) . This provides the probability that 305 sampling one study will provide an accurate estimate of the true effect size. We refer to this 306 as the probability of attaining a hit, given the sample size (p(hit $|N_x|$)). (As above, although 307 we expect this to change as a function of $\frac{1}{N}$, the exact relationship is dependent on 308 measurement noise). We next estimate effect size biases that result from aggregating across 309 experiments with statistically significant results (p<.05), under the assumption that the 310 published literature is more likely to only contain significant findings. We computed the difference between the mean effect size from significant results and the mean effect size from 312 all results, and refer to this value as the *inflation bias*. Effectively, this analysis is assessing 313 the severity of the file-drawer effect for different sizes of N. To inform understanding of 314 potential file-drawer effects, we also report the proportion of studies that rejected the null 315 hypothesis (p < .05) for N_{med} , and the N where this value reached 90% (note: this is related 316 to the observed effect size, but we report it here for clarity). 317

Last, we sought metrics that may inform whether an experiment is likely to have
yielded an imprecise effect size estimate. Effect sizes are a function of the variability of the
effect across individuals, as well as within-individual variability over trials
[@rouderPowerDominanceConstraint2018]. If either of these variability sources stem from a

non-normal distribution, mean and standard deviation estimates -and consequently effect size computations- may be impacted by the skewness and kurtosis of these data. We thus determined whether such features of the data could predict error in effect size estimates.

Error in effect size estimates were defined for each task as the distance between the 325 expected effect size value for N_{313} and each observed effect size from the N_{med} simulations. 326 For each N_{med} simulation, we also calculated the key behavioural effect for each participant 327 and computed the Pearson's skewness and kurtosis coefficients of the resulting distribution of 328 effects. To attain indices of the character of within participant variability, we computed the 329 variability, skew and kurtosis from each participant's performance across trials, and then took 330 the means of these measures across participants. The resulting variables served as predictors 331 in a multiple regression analysis, with effect size error serving as the criterion variable. If any 332 of these measures showed high levels of skew then a log transformation was applied. All 333 model residuals were checked for homoscedasticity. Note also that although skewness and kurtosis share variance as they depend in part on the same parameters, performing stepwise 335 regression yielded the same results and interpretations that we present below. 336

To buffer against interpreting over-fitted models, we performed k-fold cross-validation 337 for each multiple regression model, where k=10, and we report the mean and standard 338 deviation of the variance explained across folds. Next, we identified which regressors 339 consistently predicted effect size error across tasks. Having identified potentially useful 340 predictors, we then sought to identify problematic values of these predictors - i.e. what value 341 would suggest a problematic effect size estimate. To do this, we identified the values that 342 marked the .025 and .975 quantiles of the N_{313} effect size estimates, and using 343 zero-order correlations, sought the predictor values for N_{med} that predicted effect sizes that 344 were less than the .025 (or greater than .975) quantiles from N_{313} . We report these values 345 and the standard error of the prediction. 346

Computing Effect Sizes. To compute effect sizes for the paradigms analysed using
a repeated-measures ANOVA (AB, MT and CC), we computed partial epsilon squared (ϵ_p^2) ,

as this measure is unbiased, unlike η_p^2 (Okada, 2013). (Indeed, an earlier version of our manuscript showed that η_p^2 estimates are biased on average, even for sample sizes of N=313, 1). We use the formula for ϵ_p^2 as defined in (Carroll & Nordholm, 1975, eq 11):

$$\epsilon_p^2 = \frac{F - 1}{F + \frac{df_w}{df_b}} \tag{1}$$

where F is the F statistic for the effect, df_w is the degrees of freedom within groups, and df_b is the degrees of freedom between groups. The SRT paradigm instead uses a paired-samples design. For this paradigm we computed Cohen's d_z (see Lakens (2013), eq 6):

$$d_z = \frac{M_{diff}}{\sqrt{\frac{\sum (X_{diff} - M_{diff})^2}{N - 1}}} \tag{2}$$

where M_{diff} is the mean difference between groups, and X_{diff} is the difference score for one subject.

To facilitate our interpretation of effect sizes as small, medium or large, we refer to Cohen (1992) for ϵ_p^2 and to Gignac & Szodorai, (2016) for d_z .

Representative N. To attain an N that reflects what is commonly used for each paradigm, we surveyed the three most relevant Journal of Experimental Psychology journals (General, Human Perception & Performance and Learning, Memory & Cognition) for all articles mentioning use of any of the current paradigms. We searched back for a total of 60 experiments or back from today to 2005, whichever occurred first. We then computed the median sample size used across all experiments found from the survey. The results from the survey are presented in Table 1.

Analysis of Experimental Tasks.

387

Attentional Blink. As is typical for the field, and to ascertain the effectiveness of 367 the lag manipulation, T2|T1 accuracy was subject to a repeated measures ANOVA, with lag 368 (2, 3, 5, & 7) as the independent variable. This analysis was also applied to each k sample. 369 For each k sample, ϵ_p^2 and the resulting p value were taken for the main effect of lag. For this 370 task, and all remaining ANOVA tests, models were fit using the anova test() function from 371 the rstatix package. Where possible, the models were fit using type 3 sum of squares, owing 372 to the computational expediency and match to commercial statistical software packages. In 373 some cases, models were unable to be fit using type 3 sum of squares, owing to rank 374 deficiencies in the underlying design matrix (e.g. when one participant was drawn more than 375 twice within a sample). In these cases, models were fit using type 1 sum of squares. However, 376 as the experiment designs were fully balanced, each sum of squares type should yield the 377 same results. 378

Multitasking. To ascertain the effectiveness of the multitasking manipulation, the data were modelled using a 2 (task-modality: visual-manual vs auditory-manual) x 2 (task: ST vs MT) repeated-measures ANOVA. This analysis was also applied to each k sample; ϵ_p^2 and p are reported for both the main effect of task and the task-modality x task interaction.

Serial Response Task. To ascertain whether participants learned the repeating sequences, RTs in the final block of sequence trials (block 3) were compared to those in the final block of random trials (block 4) using a paired-samples t-test. This analysis was also applied to each k sample, and we present the resulting Cohen's d_z , and p value from each test.

Contextual Cueing. To ascertain whether participants became faster for repeat relative to novel trials over the course of the experiment (i.e. whether participants learned the statistical regularities of the repeated displays), the data were subject to a block (1:12) x condition (repeat vs novel display) repeated measures ANOVA. Specifically, learning should be evidenced by a significant block x condition interaction. This analysis was applied to each k sample, and we report ϵ_p^2 and p for the block x condition interaction.

As some studies from the contextual cueing literature suggest that the effect is better characterised by a main effect of condition thereby implying rapid learning of the statistical regularities (e.g. Peterson & Kramer, 2001; Travis, Mattingley, & Dux, 2013), we also report the ϵ_p^2 and p for the main effect of condition.

398 Results

We first present the results from the standard analyses used for each task, to show that
we replicate the classic findings from each task. The key behavioural data are presented in
Figure 2.

102 Behavioural Results

Attentional Blink. The AB data are presented in Figure 2A. Accuracy for T2|T1 was lower for early relative to late lags; accuracy for T2|T1 decreased (by around p = 0.32) when T2 was presented at lag 2, relative to lag 7. A one-way ANOVA revealed that the effect of lag was statistically significant (F (2.4, 749) = 508, $\epsilon_p^2 = 0.62$, p = 1.88e-157). Post-hoc t-tests showed that accuracy at each lag differed statistically from accuracy at each of the other lags (all p's \leq 3.68e-18). Therefore, the AB paradigm yielded the typically observed effects.

Multitasking. As anticipated, RTs were slowed for multitask relative to single task 410 conditions (see Figure 2B). Mean RTs were on average 0.31 (95% CI[0.30, 0.33]) seconds (s) 411 slower on MT trials (F(1, 312) = 2653, ϵ_p^2 = 0.89, p<.0001). There was also a significant 412 task modality (sound or visual) x task (ST vs MT) interaction (F(1, 312) = 59.4, $\epsilon_p^2 = 0.16$, p<.0001). The MT cost (MT RT - ST RT) was larger for the sound task relative to the visual task by on average 0.08 s (95% CI[0.06, 0.10]). This latter finding has been reported 415 previously (Hazeltine & Ruthruff, 2006). We continue to interrogate this effect, as it serves 416 as an example of an interaction with a small effect size. This facilitates comparisons to the 417 contextual cueing task, as reported below. 418

SRT. The results from the SRT paradigm are presented in Figure 2C. Participants 419 learned the repeating sequence; RTs were on average 0.049 s faster (95% CI [0.046, 0.051]) 420 for the sequence relative to the random condition (t(312) = 33.60, $d_z = 1.90$, p = 1.13e-105). 421 Contextual Cueing. Participants learned the repeat displays over blocks (see Figure 422 2D); the RT data showed a significant albeit small block x condition interaction (F (10.12, 423 3158.9) = 4.80, ϵ_p^2 = 0.01, p = 6.01e-07). There was no statistically significant difference 424 between RTs for repeat and novel displays for block 1: (t (312) = 0.53, p = 0.60, μ difference 425 = 0.01 s, sd: 0.20). However, by block 12, RTs for repeat displays were on average 0.04 s426 faster than novel displays (sd: 0.14, t (312) = 5.33, p = 1.87e-07. There was also a significant 427 and larger main effect of block (F(5.03, 1567.97) = 131.08, $\epsilon_p^2 = 0.29$, p = 1.07e-116). and a 428 significant main effect of condition (F(1.00, 312.00) = 32.78, ϵ_p^2 = 0.09, p = 2.42e-08). 429

30 Effect Sizes

Summary Statistics and Precision Loss. Across tasks, we observed a range of 431 small to large effect sizes $(epsilon_p^2: .01 - .9)$, thus we are able to characterize the extent of precision loss across a range of effect size scenarios. For studies run with N_{med} , the range of 433 precision losses we observed was 1.78 - 4.16, suggesting that caution is warranted when basing power calculations on the outcomes of a small number of studies. The N required to 435 reduce precision loss to < 2 ranged from 36 - 82. For both the interaction effects currently 436 studied (MT and CC), the effect size distributions for N_{med} spanned from below to above 437 zero, suggesting that differing conclusions may be reached across studies. Specifically, when 438 the effect size is less than zero, the direction of the effect has the opposite sign. The observed 439 power to reject the null hypothesis ranged from p=.35 - 1, suggesting areas where there may 440 be missing literature owing to publication bias. We next report these details for each task. 441 **Attentional Blink.** The AB effect was large (see Figure 3A); $N_{313} \epsilon_p^2 M = 0.62$ 442 (SD: 0.03, LB: 0.57, UB: 0.67). The simulated effect sizes for N_{med} (N_{25}) produced the same 443 mean effect size estimate (M: 0.62, SD: 0.06, LB: 0.48, UB: 0.74, see Figure 3B). With

regard to extent of precision loss; the qq-ratio for N_{med} was 2.38. The qq-ratio for small N was ~3 ($N_{13}=3.06, N_{15}=2.98$), and reached < 2 at N_{42} ($N_{36}=2.09, N_{42}=1.81$). The remaining qq-ratios are presented in Figure 5.

Across all N, the probability of rejecting the null hypothesis was 1.

Multitasking.

448

449

Main effect of task condition. For the MT paradigm, the main effect of task condition was large $(N_{313} \epsilon_p^2 M = 0.90, SD: 0.01, LB: 0.87, UB: 0.92)$, and the simulated effect sizes for N_{med} (N_{42}) produced the same mean effect size estimate (M: 0.90, SD: 0.03, LB: 0.84, UB: 0.94, see Figure 3D). With regard to precision loss, the qq-ratio for N_{med} was 1.89.

Comparable to the AB, qq-ratio for small N was ~ 3 $(N_{13} = 2.97, N_{15} = 3.03)$, and was < 2 for N_{36} $(N_{30} = 2.12, N_{36} = 1.96)$. The remaining qq-ratios are presented in Figure 5.

Across all N, the probability of rejecting the null hypothesis was 1.

Task condition by modality interaction. The task condition x modality interaction 457 achieved a medium effect size (N_{313} ϵ_p^2 M=0.17, SD: 0.06, LB: 0.06, UB: 0.30, see Figure 458 3E), and the simulated effect sizes for N_{med} produced the same mean effect size estimate (M: 459 0.17, Mdn: 0.16, SD: 0.12). However, the LB and UB quantiles from N_{med} crossed zero (LB: 460 -0.02, UB: 0.43, see Figure 3F), suggesting that using N_{med} will sometimes produce differing 461 inferences with regard to the effect size, compared to N_{313} . With regard to precision loss, the 462 qq-ratio for N_{med} was 1.78. The qq-ratio for small N was ~2.75 ($N_{13} = 2.88, N_{15} = 2.72$), 463 and reached < 2 at N_{36} ($N_{30} = 2.00$, $N_{36} = 1.87$). The remaining qq-ratios are presented in 464 Figure 5. 465

The probability of rejecting the null hypothesis at N_{med} was 0.79. A sample size of N_{82} was required to achieve statistical power of > 90 % ($N_{69} p = 0.90$, $N_{82} p = 0.95$).

Serial Response Task. For the SRT, the effect of sequence vs random was large $(N_{313} d_z M: 1.93, SD: 0.21, LB: 1.53, UB: 2.33, Figure 4A)$. Here, there was disagreement between N_{313} and N_{med} (N_{36}) regarding the means of the simulated effect size distributions

 $(N_{med} d_z M = 2.02, SD: 0.44, LB: 1.22, UB: 2.86, see Figure 4B)$. With regard to precision loss, the qq-ratio for N_{med} was 2.05. The remaining qq-ratios are presented in Figure 5. The qq-ratio for small N was ~ 3.5 ($N_{13} = 3.62, N_{15} = 3.35$), and reached under 2 at N_{42} ($N_{36} = 2.05, N_{42} = 1.88$).

Across all sampled N, the probability of rejecting the null hypothesis was 1.

$Contextual\ Cueing.$

476

496

Block x Condition Interaction. The block x condition interaction effect was on the 477 boundary between very small and small (N_{313} ϵ_p^2 M: 0.02, SD: 0.01, LB: 0.01, UB: 0.04, Figure 4C). There was a minor discrepancy between the N_{313} and N_{med} (N_{25}) means, but 479 the N_{med} Mdn agreed (M: 0.03, Mdn: 0.02, SD: 0.03). Similar to the SRT task, the effect 480 size distribution for N_{med} included zero (N_{med} LB: -0.02, UB: 0.11), thus experiments with 481 N_{med} may sometimes motivate different conclusions to N_{313} . Specifically, when the effect size 482 is below zero, it would be concluded that repeating displays leads to a slowing of RTs (rather 483 than speeding RTs), relative to novel displays. There was also a greater extent of precision 484 loss at N_{med} than was observed for other tasks (qq-ratio: 4.16). The qq-ratio for small N 485 was ~ 6 ($N_{13} = 6.41$, $N_{15} = 5.64$), and reached under 2 at N_{82} ($N_{69} = 2.08$, $N_{82} = 1.84$). The 486 remaining qq-ratios are presented in Figure 5. 487

The probability of rejecting the null hypothesis at N_{med} was p=0.35. A sample size of N_{82} was required to achieve statistical power of > 90 % (N_{69} p=0.90, N_{82} p=0.95).

Main Effect of Condition. The main effect of condition was large $(N_{313} \epsilon_p^2 M: 0.31, SD: 0.03, LB: 0.25, UB: 0.37,$ see Figure 4E). There was a minor discrepancy between the mean estimates for N_{313} and N_{med} (M: 0.33, Mdn: 0.32, SD: 0.08, LB: 0.20, UB: 0.47, see Figure 4F). Precision loss was comparable to the SRT (qq-ratio: 2.19). The qq-ratio for small N was ~2.8 $(N_{13} = 2.82, N_{15} = 2.75)$, and reached under 2 at N_{36} $(N_{30} = 2.19, N_{36} = 1.97)$. The remaining qq-ratios are presented in Figure 5.

The probability of rejecting the null hypothesis at N_{med} was p = 0.39. A sample size of

 N_{136} was required to achieve statistical power of > 90 % (N_{115} p = 0.97, N_{136} p = 0.99).

Impacts of imprecision and missing literature. Having characterized the effect 498 size distributions for each task, we next sought to determine the impact of effect size 499 imprecision when basing power calculations on a similar study that uses N_{med} , and the 500 extent to which effect size estimates could be inflated in cases where there may be missing 501 information owing to publication bias. For the former, we computed p(hit|N); for the AB, 502 MT and SRT paradigms, the p(hit| N_{med}) was ~0.66 (AB: 0.65, MT tc: 0.67, MT tc x m: 503 0.67, SRT: 0.65). This suggests that sampling a similar study will produce a reasonable a 504 priori effect size estimate 2/3 of the time (Note: it is interesting that the AB, MT and SRT 505 fields appear to have converged on an N_{med} that puts them on a comparable footing for 506 hitting the best effect size. Indeed, if the MT and SRT fields used the same sample size as 507 the AB field, the p(hit N_{25}) ratios for the three effects would be ~0.57 (MT tc: 0.59, MT tc x 508 m: 0.54, SRT: 0.57)). For the CC paradigm, the p(hit| $N_{med} = \sim .48$ (b x c: 0.40, c: 0.55). 509 This suggests that basing effect size estimates on a similar CC study will result in an 510 appropriately powered study 50% of the time. The remaining p(hit N_x) are presented in 511 Figure 6.

Next, we estimate the *inflation bias* that is incurred by using a given N. Here we focus on the MT and CC paradigms, as they contained effects where the null was not consistently rejected at N_{med} . For the MT task, the task condition x modality inflation bias for N_{med} was 0.04 ϵ_p^2 . No inflation bias was present for the main effect of task condition (all N=0). For the CC, the block x condition interaction inflation bias at N_{med} was 0.03 ϵ_p^2 , for the main effect of condition the N_{med} inflation bias was nominal (-0.003 ϵ_p^2). These and the remaining inflation bias estimates are presented in Figure 7.

Predicting error in effect size estimates. Last, we determined which aspects of between and within-participant variability were predictive of imprecise effect size estimates.

Multiple-regression models showed that between 10-40% of the variance in effect size errors could be predicted by the skew and kurtosis of the behavioural effect across participants, as

well as the mean variability, skewness and kurtosis within participants for all the behavioural effects (mean R^2 s (sd): AB: 0.39 (0.08), MT main effect: 0.09, (0.05), MT interaction: 0.11 (0.04), SRT: 0.22 (0.09), CC main effect: 0.19 (0.08) apart from the block x condition effect from the CC task, where the model accounted for only 1% of the data. This supports the notion that non-normal sources of data may contribute to error in effect size estimates.

529 Discussion

We simulated 1000 bootstrapped experiments across 20 Ns ranging from 13 to 313. 530 For each paradigm and from each set of simulations, we determined the impact of N on error in effect size estimates. In doing so, we were able to quantify a range of effect sizes that 532 researchers can consider when performing power analyses, particularly when using the AB, 533 MT, SRT or CC paradigms. We determined precision loss in effect size estimates as a function of N and found that decreasing N_{max} to N_{med} inflated the range of effect sizes by 535 factors ranging between 1.78-4.16. We also computed the probability of attaining an accurate 536 effect size estimate (defined as falling between the .025 and .975 quantiles of N_{max}), and 537 found that sampling a single study would result in a reasonable estimate on between 40-67% 538 of samples. Last we computed the inflation bias for effects that carried less than 90% power 539 at N_{med} . We found that inflation biases ranged from a nominal to small effect (ϵ_p^2 : -.003-.03). 540 These findings can inform study planning, study interpretation and theory development. 541

Study Planning. Our findings have practical relevance for study planning. A researcher planning a study using the Attentional Blink, who only has resources to test 50 participants, can now a priori determine that they have 100% power to reject the null hypothesis. They can also determine that their observed effect size may be inflated by a factor of 1.78, and that their effect size estimate will be comparable to a study with several hundred people 77% of the time. Thus, the researcher can move to designing studies that produce an effect size estimate that they believe is sufficiently accurate to be a useful contribution to the field. They are also able to identify points of diminishing returns, beyond

which testing extra participants may produce incremental gains. For example, by examining
the relationship between the qq-ratio and N, they can determine the point at which they
believe the cost in resources outweighs the benefits of precision gain. The information
presented above allows such informed decision-making to be conducted for the AB, MT, SRT
and CC tasks.

These findings complement the insights offered by previous simulation studies into the 555 factors influencing effect size estimates. Previous simulation work has highlighted conditions 556 that cause bias in effect size estimates (Gelman & Carlin, 2014; e.g. Lane & Dunlap, 1978; 557 Okada, 2013: Troncoso Skidmore & Thompson, 2013) and the consequences for power 558 calculations (Albers & Lakens, 2018; Anderson, Kelley, & Maxwell, 2017), by generating 559 data-sets under simplifying conditions such as using between subjects designs or using lower 560 and fewer samples of N. Collectively, these studies have determined which effect size 561 measures provide unbiased estimates (e.g. ϵ_p^2 vs η_p^2), that effect size estimates are likely to be 562 inflated due to publication bias and low statistical power, and that the process of study 563 design should account for uncertainty in the magnitude and direction of anticipated effect 564 sizes. However, it can be challenging to determine the uncertainty around effect size 565 estimates and the impact of differing N on that uncertainty without quantifications of the expected effect size, and the variability around that effect size, for a given field of study. By taking the current step away from simplifying data generating conditions, and instead 568 simulating experiments based on data from specific paradigms with more complex designs, we provide insight into the uncertainty regarding effect size estimates for ecologically valid data taken from the AB, MT, SRT and CC paradigms. 571

Study Interpretation. Our findings also offer insight into the interpretation of
existing studies using the AB, MT, SRT and CC paradigms. Researchers evaluating existing
studies can use the current findings to estimate the potential imprecision of a given effect
size, and can accordingly weight their belief in consequent theoretical assertions. The current
findings also enable (largely positive) evaluations of the broader literature for each paradigm.

Statistical power was largely very strong, apart from for interactions, which involved small or 577 medium effects. This suggests that the published literature will likely cumulatively reflect a 578 reasonable effect size estimate, across all N, when the effect under study is a main effect. 579 However, for interaction effects (for which we only saw very small to medium effect sizes $[\epsilon_v^2]$: 580 .02-.17), we consistently found that ~82 participants were required to achieve > 90% power, 581 which was far above the N_{med} for each paradigm. It follows that interactions would be 582 relatively under-powered since data is being divided into more bins, and this accords with 583 other observations that current practices result in low statistical power for interaction effects 584 (e.g. Lakens & Caldwell, 2021). However, our survey of the field suggests that investigation 585 of interaction effects with low N remains common practice when measuring attention, 586 executive function and implicit learning. The current findings demonstrate that cumulative 587 approaches would be hampered by current practices in characterizing interaction effects (at least in the case of MT and CC).

We believe these findings offer new insights when considering what constitutes a well 590 powered study for investigations into attention, executive function and implicit learning. The 591 current findings show that achieving statistical power to reject the null hypothesis is either 592 trivially easy, or, in the case of very small effects (as we observed for CC b x c), is inevitable with sufficient N. Therefore, demonstrating rejection of the null hypothesis has relatively little to offer if the goal is to develop theory and leverage insights from cumulative science 595 (Chen et al., 2019; Cumming, 2014; Gelman & Carlin, 2014; Lorca-Puls et al., 2018). Here 596 we show that if a given field can pool data, or collectively provide the appropriate simulation 597 parameters, then it is possible to plan research studies with the aim of producing an effect 598 size estimate that has an acceptable level of precision. Of course, there are no pre-defined 599 rules regarding what is a tolerable level of precision. This is something that may need to be 600 defined on a case by case basis. 601

Just as knowing about the distributional properties of effect sizes observed across many 602 replications provides information about study design and interpretation, so too can

considering the distributional qualities of observed p-values. The p-value is itself a random 604 variable that will vary from experiment to experiment (e.g. Chen et al., 2019), yet this 605 variation is rarely considered when researchers report a single p-value for each reported effect. 606 Understanding exactly how a p-value may vary across replications can help identify where 607 there may be missing literature owing to publication bias, or uncertainty regarding the 608 rejection of the null hypothesis (e.g. Nolan, Vromen, Cheung, & Baumann, 2018). Moreover, 609 although it is known that p-values are inversely related to effect size, the relationship is both 610 non-linear and non-trivial to compute as it depends on other factors such as the sample size, 611 the underlying data type (e.g. independent vs dependent) and the statistical test (Faul, 612 Erdfelder, Lang, & Buchner, 2007). The current simulation approach could also be employed 613 to better map the relationship between N and p-values, for varying effects. This can yield 614 insights into uncertainty over p-values and assist with interpretation of research findings. We provide the p-value data from the current simulations as Supplemental figures ² to help with 616 this endeavor. 617

Theory Development. The current simulation approach can also inform theory 618 development. In the case of implicit learning, our results showed that for the CC paradigm, 619 the block x condition interaction effect was very small (ϵ_p^2 : .01-.04). This may be because the 620 effect is very small across all variations of the paradigm, or that the current design 621 parameters may not effectively measure the effect. The current paradigm was modeled on 622 the seminal demonstration (Chun & Jiang, 1998). Nonetheless, there may be critical design 623 parameters that with modification, elicit a larger (and more positive) range of interaction 624 effects. Applying the current simulation approach to data collected across varying 625 implementations of the CC paradigm can yield insights into what produces the effect, and 626 consequently can help refine theory regarding the causes of the effect. 627

The current approach of using a large data-set also offers insight into the impact of

² See https://github.com/kel-github/Super-Effects/tree/master/doc/supp-figs

increasing individual variation while holding measurement error relatively constant, for each 629 paradigm under study here. Hopefully, at N_{313} the contribution of individual variation is 630 relatively low compared to the measurement error. Given this, the currently observed 631 comparable rates of change for the qq-ratio and p(hit|N) values across paradigms may be 632 unsurprising. This consistency may be of some value when quantifying the impact of 633 individual variation on predicted effect magnitudes. Furthermore, the range of effect sizes 634 observed for experiments at N_{313} provides an estimate of measurement error that could be 635 built into quantitative predictions for the AB, MT, SRT and CC effects. 636

Limitations. It remains an open question whether the current findings generalize 637 beyond the paradigms and participant pool used here. There are some suggestions of 638 generalizability of the current observations across tasks that should be investigated in future 639 research. Across all the ϵ_p^2 findings, the standard deviations at N_{313} were small (SDs: .01-.03), and each SD doubled or tripled as a function of moving from N_{313} to N_{med} . Therefore, it is possible that effect sizes such as ϵ_p^2 will show a comparable reduction in variability as N increases to the hundreds, across all paradigms. If this were found to be true, then researchers could apply the rates of change observed here to effect size estimates from their own field of study in order to determine the N required to achieve a tolerable level of precision. Moreover, changes in p(hit|N) and qq-ratio rates were comparable across N for all effects, regardless of size, suggesting invariance to the measurement differences across 647 paradigms. Future research should determine the extent to which these rates were dependent 648 upon the current sample of N_{313} , which was arguably homogeneous with regard to 649 population characteristics. Indeed, it is pertinent to determine the extent to which our 650 results would hold with more heterogeneous samples. For example, estimates of effect sizes 651 may be more variable under less constrained conditions, such as when community sample 652 participants complete online studies. Future work should determine the extent to which 653 study design choices may hamper precise effect size estimates in such groups. 654

A further limitation is that the p(hit|N) and qq-ratio values were dependent on the

range of effect sizes observed at N_{313} . The results may be different if we had sampled N_{1000} (for example). Thus interpretation of the current findings is dependent on how willing the researcher is to assume that several hundred participants is a sufficient representation of 'as good as it gets'. Given the small ranges of effect sizes observed for N_{313} , we certainly think this is a reasonable place to start.

661 Conclusions

By simulating experiments across varying N for popular paradigms from the study of 662 attention, executive function and implicit learning, we are able to provide insights into the 663 precision of effect size estimates that are unknowable from simulation approaches that make 664 simplifying assumptions regarding the data. Using the current approach, we can identify the 665 mean effect size and the variability of that effect size, under the best case scenario. This 666 allows us to quantify the change in precision of effect size estimates with varying N. We 667 identify that using a typical N can double imprecision of effect size estimates, and 668 characterize to what extent this reduces the chances that a single study will provide a 669 reasonable effect size estimate. In the case of the small effect sizes observed here, inflation 670 bias can amount to the equivalent of a small effect size. Amassing large data-sets to allow 671 characterisation of error in effect size estimates is a useful exercise when seeking to plan 672 studies that facilitate cumulative science. 673

Table 1 Typical N found from literature survey. n exp = number or experiments, med N = median N

task	n exp	med N
AB	60	24
MT	60	40
CC	49	24
SRT	60	34

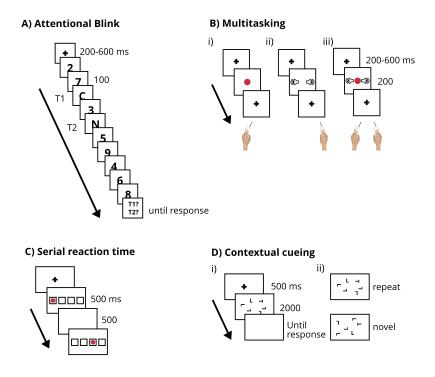

Figure 1. Task battery. A) Attentional Blink Paradigm (AB). Participants report the two letter targets from the rapid serial visual presentation of numbers and letters. B) Multitasking Paradigm (MT). Participants discriminate the colour of a disc, a complex tone, or both. C) Serial reaction time task (SRT). Participants respond to one of four stimuli, each mapped to a spatially-compatible button press. Unknown to participants, for half of the experimental blocks, the stimulus follows a repeating sequence. D) Contextual Cueing Paradigm (CC). i) Participants perform an inefficient visual search task where they search for a rotated T among L distractors. ii) Unknown to participants, half of the search arrays are repeated throughout the course of the experiment.

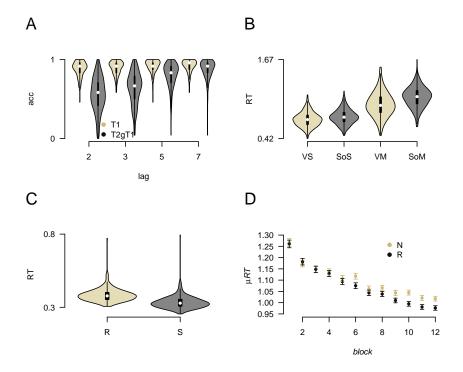

Figure 2. Behavioural Results. A) Attentional Blink Paradigm (AB). Accuracy (acc) for T2|T1 was lower at early lags, relative to later lags. Note that T1 accuracy is also plotted. B) Multitasking Paradigm (MT). RTs were slowed for multitask (M) conditions, relative to single-tasks (S). This difference was larger for sound tasks (So) than for visual (V) tasks. C) Serial Response Task (SRT). In the second half of the experiment, RTs were faster in the sequence (S) relative to the random (R) condition. D) Contextual Cueing (CC). RTs were faster for the repeat (R) than for the novel (N) displays, and this difference became larger throughout the course of the experiment.

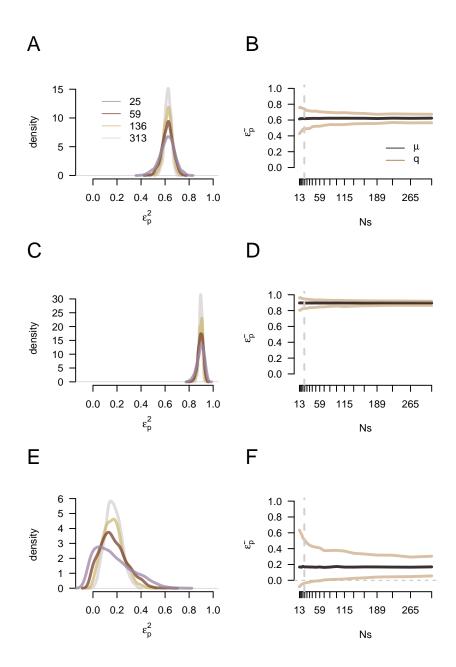

Figure 3. Effect size distributions for the AB and MT paradigms. A) AB: Partial epsilon sq distributions for selected N for the main effect of lag. B) Showing the mean partial epsilon squared, and the UB and LB quantiles [.025, .975], for the main effect of lag, across N (AB). C) MT: Same as in A, but for the main effect of task condition (MT). D) Same as in B, for the main effect of task condition (MT), E) As in C, but for the task x modality interaction (MT), E) As D, but for the MT task x modality interaction

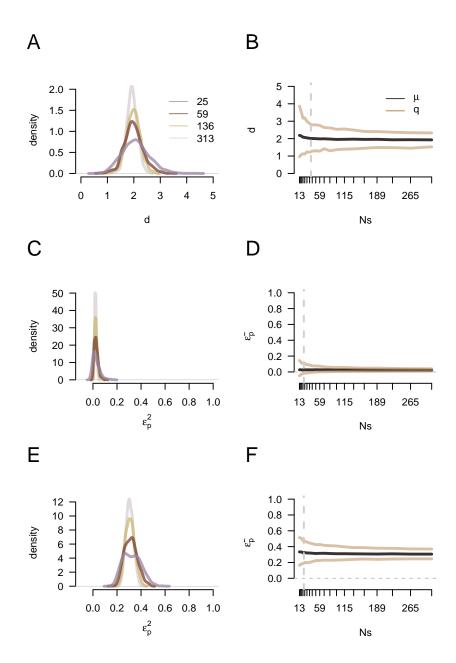

Figure 4. Effect size distributions observed for the SRT and CC paradigms. A) SRT: Cohens dz for the effect of sequence learning, for selected N. B) Showing the mean dz, and the UB and LB quantiles [.025, .975], for the effect of sequence, across N (SRT). C) CC: Same as in A, but for the block x condition interaction. D) Same as in B, for the block x condition interaction (CC), E) As in C, but for the main effect of condition (CC), E) As D, but for the main effect of condition (CC)

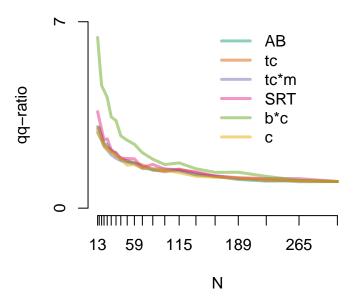

Figure 5. QQ-ratios plotted by N for each task effect. AB: Attentional Blink, tc: main effct of task condition from the MT paradigm, tc*m: trial condition x modality interaction, SRT: Serial Response Task, b*c: block x condition interaction from the CC task, c: main effect of condition from the CC task.

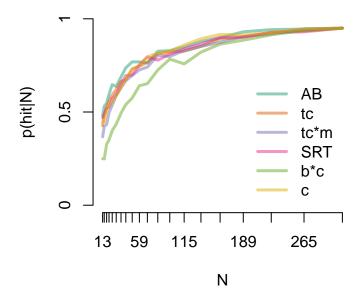

Figure 6. probability of a single study producing an effect size estimates that are within the LB and UB for the best estimate (p(hit|N)), plotted by N for each task effect. AB: Attentional Blink, tc: main effect of task condition from the MT paradigm, tc*m: trial condition x modality interaction, SRT: Serial Response Task, b*c: block x condition interaction from the CC task, c: main effect of condition from the CC task.

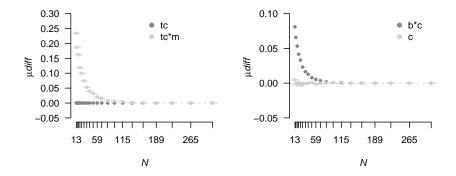

Figure 7. Inflation bias scores plotted by N for the A) the task condition and task condition x modality interactions for the MT paradigm, and B) the block x condition interaction and main effect of condition from the CC paradigm. IB: Implicit Bias, tc: task condition, tc*m: task condition x modality, b*c: block x condition interaction, c: main effect of condition. Error bars reflect pooled standard error of the difference.
