Abstract

Accurate quantification of effect sizes has the power to motivate theory, and reduce misinvestment of scientific resources by informing power calculations during study planning. However, a combination of publication bias and small sample sizes ($\sim N = 25$) hampers certainty in current effect size estimates. We sought to determine the extent to which sample sizes may produce error in effect size estimates for four commonly used paradigms assessing attention, executive function and implicit learning (Attentional Blink (AB), Multitasking (MT), Contextual Cueing (CC), Serial Response Task (SRT)). We combined a large data-set with a bootstrapping approach to simulate 1000 experiments across a range of N (13-313). Beyond quantifying the effect size and statistical power that can be anticipated for each study design, we demonstrate that experiments with lower N may double or triple information loss. We also show that basing power calculations on effect sizes from similar studies yields a problematically imprecise estimate between 40-67% of the time, given commonly used sample sizes. Last, we show that skewness of inter-subject behavioural effects may serve as a predictor of an erroneous estimate. We conclude with practical recommendations for researchers and demonstrate how our simulation approach can yield theoretical insights that are not readily achieved by other methods; such as identifying the information gained from rejecting the null hypothesis, and quantifying the contribution of individual variation to error in effect size estimates.

Introduction

Despite the complexity involved in disentangling the processes that underpin cognition, decision making regarding experimental outcomes is often made on binary (i.e. pass or fail) terms, across the psychological, neuroscientific and biomedical sciences (Szucs & Ioannidis, 2017). Theoretical predictions are often specified in terms of the presence or absence of a given effect, and a yes/no decision is made about whether the null hypothesis (usually a hypothesis of null differences) can be rejected. It seems unlikely that such binary decision-making will be sufficient to disentangle the myriad functional systems that comprises the brain's processes. An alternate approach is to develop theory and models that predict the magnitude of the effect. Providing predictions in terms of effect size magnitude prompts theorists to consider the variability as well as the presence of predicted effects, and is demonstrably a useful metric when considering practical relevance (Funder & Ozer, 2019). Such magnitudes are often characterised as an effect size: a standardised measure that reflects the extent to which an effect, such as a mean difference between two conditions, is expected to generalise to the population (Cohen, 1988).

A prediction of effect magnitude is easier to disprove than a binary outcome, and therefore constitutes a more desirable prediction for theory testing (Popper, 1959). To move towards theories that predict changes in effect size magnitude, it is helpful to gain an understanding of how much insight is yielded from our current effect size estimates; i.e. how well are we currently quantifying effect sizes, and should we increase sample sizes to quantify them better? Indeed, recent work suggests that insufficiently powered studies are at increased risk of producing effect size estimates that are either inflated in magnitude, or are in the incorrect direction (Chen et al., 2019; Gelman & Carlin, 2014). Here we seek to address how well we currently characterise effect sizes in the study of cognition, using some established paradigms in the fields of attention, executive function and implicit learning; namely the Attentional Blink (AB, Raymond, Shapiro, & Arnell, 1992), Multitasking (MT,

65 Schumacher et al., 2001), Serial Response Task (SRT, Nissen & Bullemer, 1987), and

66 Contextual Cueing (CC, Chun & Jiang, 1998) paradigms.

67   Accurate quantification of effect sizes is also desirable for study planning, as effect sizes

68 form the foundation of *a priori* power calculations (Cohen 1988). Here the researcher

69 determines the sample size (N) required to achieve sufficient power to correctly reject the

70 null hypothesis. The importance - and difficulty - of accurately determining the anticipated

71 effect size has been considered extensively elsewhere (Cohen, 1988; Gelman & Carlin, 2014;

72 Albers & Lakens, 2018; Cumming, 2014;, Egger, Smith, Schneider, & Minder, 1997; Guo,

73 Logan, Glueck, & Muller, 2013; Lakens, 2013; Szucs & Ioannidis, 2017; Westfall, Kenny, &

74 Judd, 2014). Standard approaches of determining an anticipated effect size involve

75 consulting a meta-analysis, basing effect-size estimates on a few similar studies (incomplete

76 sampling), or determining the smallest effect that is of theoretical relevance (e.g. Gelman &

77 Carlin, 2014). What remains somewhat less considered is the utility of knowing how effect

78 size estimates may vary across replications of an experiment (e.g. Cumming, 2014;

79 Lorca-Puls et al., 2018), i.e. what are the distributional properties of the effect size, given a

80 field that uses a comparable N across experiments?

81   The answer to this question can facilitate both study planning and theory development.

82 A paradigm that elicits a small effect that manifests with low variability across replications

83 may be considered a more desirable target for theory and model development than a

84 paradigm that produces the same mean effect size but with wider variability. With regard to

85 study planning, identifying the lower bound of an expected effect size facilitates computation

86 of the N required to achieve sufficient statistical power under the worst case scenario

87 (Gelman & Carlin, 2014). Understanding how effect sizes vary across replications with a

88 given N also allows computation of the likelihood that any single study has produced a

89 reasonably accurate estimate, which can inform the researcher who may be computing

90 anticipated effect sizes on the basis of one or a few similar studies. There is also utility in

91 knowing to what extent variability in effect size observations reduces when larger N are used

instead. There may be an upper bound on the accuracy with which a particular effect can be estimated, for example, when the construction of a paradigm introduces a certain level of noise or measurement error that is larger than variation at the level of the individual. Consequently, there may be a point of diminishing returns, where the cost of recruiting extra N will outweigh the gains in accuracy of effect size estimation.

Quantifying the range of effect sizes that may be observed across experimental replications is not trivial. Indeed, it has been noted that the largest challenge in experimental design is the prior identification of a plausible range of effect sizes (Gelman & Carlin, 2014). Meta-analytic and incomplete sampling approaches for determining an expected effect size are hampered by the quality of the existing literature (Brand, Bradley, Best, & Stoica, 2008; Friston, 2012; Gelman & Carlin, 2014; Lane & Dunlap, 1978; Lorca-Puls et al., 2018). A recent survey of 900 effect sizes across psychology disciplines showed that effects from non-pre-registered studies were much larger than pre-registered studies ($r = 0.36$ vs 0.16, Schäfer and Schwarz (2019)) suggesting that prior to pre-registration, under-powered studies were contributing inflated effect size estimates to the psychology literature. Although multiple correction methods have been developed within the meta-analytic framework to account for biases due to missing literature (Schmidt & Hunter, 2015), they typically involve assumptions about the sources of missing data, which can never be fully tested (McShane, Böckenholt, & Hansen, 2016; Wiernik & Dahlke, 2020). Thus even if one were to define an expected effect size using corrected meta-analyses (if available), there is much to gain from corroborating meta-analytic results with alternate methods that can guarantee a lack of bias in the available dataset. It is also difficult to determine, on the basis of existing literature - such as when using meta-analysis - how conclusions about effect sizes would differ if a given field of study was different, e.g. how much published literature is likely to be missing if a larger N was used as standard?

Simulation studies offer the opportunity to ask how well a field is currently quantifying effect sizes, and how a field's estimate of an effect size would change with differing levels of

119 statistical power. Typically, simulation studies generate data under some simplifying

120 assumptions about the data generation process (e.g. Albers & Lakens, 2018; Hedges, 1982;

121 Lane & Dunlap, 1978; Troncoso Skidmore & Thompson, 2013; Westfall et al., 2014).

122 Although this work is necessary for informing how effect size estimates behave under varying

123 conditions where ground truth is known, it is challenging to anticipate all the complexities of

124 data from the repeated-measures designs used across a range of phenomena and processes,

125 such as in the study of attention, executive function and implicit learning. Such data are

126 often not normally distributed and carry varying levels of covariance between conditions.

127 Thus, there remains a question mark over the extent to which the results from simulation

128 work generalizes to real-world data. An alternative method is to simulate experimental

129 outcomes by bootstrapping smaller samples from larger, real data-sets (e.g. Lorca-Puls et al.,

130 2018). This approach offers the opportunity to characterize the distributional qualities of

131 effect sizes estimated from high-dimensional data-sets, using varying levels of N, while

132 maintaining ecological validity.

133 In the current study, we applied the latter simulation approach to characterize effect

134 size distributions yielded from the study of cognition. Participants ($N = 313$) completed a

135 battery of cognitive tasks (AB, MT, SRT and CC) originally assembled to test the

136 relationship between attention, executive function and implicit learning. For each paradigm,

137 we simulated 1000 bootstrapped experiments across 20 Ns ranging from 13 to 313. For each

138 paradigm and from each set of simulations, we determined the impact of N on error in effect

139 size estimates. We asked how much variability of effect size estimates changes as a function of

140 N, and sought to identify a point at which increasing N may offer lower gains for improving

141 effect size estimates. We next determined how likely it is that a study will produce an effect

142 size estimate with sufficiently low error, as a function of N. We also sought to determine the

143 impact of N on the potential for missing literature for each paradigm, given the case of

144 publication bias. Last, we identified data features that predict error in effect size estimates,

145 beyond the mean and standard deviation measures of which they are a function. Such

features may serve as a flag for whether data from a single experiment may be susceptible to error in effect size estimates. We focused on the skew and kurtosis of inter- and intra-subject effects, as such measures can bias mean and variance estimates when datasets violate normality assumptions, yet remain undiscussed in simulation studies that assume normality. The results motivate guidelines for study design and interpretation, not only for future AB, MT, SRT and CC studies, but also more broadly for the investigation of cognition.

Methods

Participants

The current study used a data set collected for a different pre-registered project examining the relationship between executive function and implicit learning. This data set contains performance measures from $N = 313$ participants. Participants were undergraduate students, aged 18 to 35 years old (mean = 20.14 yrs, sd = 3.46). Of the total sample, 208 reported being female, and 269 reported being right handed. Participants received course credits as compensation. All procedures were approved by The University of Queensland Human Research Ethics Committee and adhered to the National Statement on Ethical Conduct in Human Research.

Apparatus

Experimental procedures were run on an Apple Mac Minicomputer (OS X Late 2014, 2.8 GHz Intel Core i5) with custom code using the Psychophysics toolbox (v3.0.14) (Brainard, 1997; Pelli, 1997) in Matlab v2015b. Participants completed 7 tasks; Attentional Blink (AB), Multitasking (MT), Contextual Cueing (CC), Serial Response Task (SRT), Visual Statistical Learning (VSL), Operation Span task and a Stop Signal Inhibition task. Only the data from the AB, MT, CC and SRT are reported here. We opted not to report

169 the VSL, OSPAN or Stop Signal data as their design did not lend themselves to the

170 computation of a standardised effect size.

Procedures

172   Across all tasks, participants sat approximately 57 cm from the monitor. An overview

173 of the task procedures is presented in Figure 1. Details regarding each of the task protocols

174 are presented within each section below.

175   **Attentional Blink (AB).**   The AB task taps limitations in the deployment of visual

176 information processing over time. Participants are instructed to detect two targets from a

177 rapidly presented series of visual items. Accuracy for the second target is poorer if it appears

178 closer in time to the first target (at early lags, from lag 2 onwards), relative to further apart

179 in time (Raymond et al., 1992).

180   ***Protocol.***   The AB protocol was the same as that reported in Bender et al (2016).

181 Each trial began with a black fixation cross in the center of a gray screen [RGB: 128, 128,

182 128] for a variable interval of 200-600 ms. On each trial, letter targets and digit distractors

183 were presented centrally for 100 ms in rapid serial presentation. The eight distractors were

184 drawn without replacement from the digits 2-9. The target letters were randomly selected

185 from the English alphabet, excluding I, L, O, Q, U, V and X. The first target (T1) was

186 presented third in the series (serial position 3), and T2 was presented at either lag 2 (200

187 ms), 3 (300 ms), 5 (500 ms) or 7 (700 ms) relative to T1. All stimuli subtended 1.72 x 2.31 °

188 (w x h) visual angle. Participants were instructed to make an unspeeded report of the

189 identity of both targets at the end of each trial. Participants completed 24 practice trials

190 and four test blocks of 24 trials. For the current analysis we calculated T2 accuracy, given

191 that T1 was correctly reported (T2|T1), for each lag.

192   **Multitasking (MT).**   MT paradigms tap the performance costs incurred when

193 individuals attempt to perform more than one task concurrently. Participants are instructed

194 to complete two simple sensorimotor tasks as accurately and quickly as possible under single

195 or multitask conditions. RTs to the constituent tasks are typically slowed for multitask

196 relative to single task conditions (see Pashler (1994), for a review).

197   ***Protocol.***   The MT protocol was previously reported in Bender et al (2016). Each

198 trial began with a black fixation cross presented in the center of a gray screen [RGB: 128,

199 128, 128] for a variable interval of 200-600 ms. Next either one of two coloured circles [red,

200 RGB: 237, 32, 36 or blue, RGB: 44, 71, 151] or one of two sounds (complex tones taken from

201 Dux, Ivanoff, Asplund, & Marois, (2006)), or both (circle and sound) were presented for 200

202 ms. The coloured circle subtended 1.3° visual angle. Participants were instructed to respond

203 to all tasks as quickly and accurately as possible, by using the appropriate key presses ['A' or

204 'S' for left hand responses, 'J' or 'K' for right hand responses, with the task-hand mapping

205 counterbalanced across participants]. The MT protocol consisted of 4 blocks of 36 trials,

206 with each trial type (single-task [ST] visual, ST auditory or MT) randomly mixed within

207 blocks. Participants completed the MT protocols after completing two ST blocks as practice,

208 one for the visual task and one for the auditory task. We analysed mean response times

209 (RTs) to each task x modality condition.

210   **Serial Response Task (SRT).**   The SRT paradigm taps sensorimotor sequence

211 learning; specifically the extent to which individuals speed up responses when cue stimuli

212 follow a predictable sequence, relative to when cue stimuli are presented randomly (Nissen &

213 Bullemer, 1987). As participants receive no explicit instructions or cues regarding the

214 sequence, it has been assumed that the SRT taps implicit sequence learning (Nissen &

215 Bullemer, 1987), although the extent to which performance gains reflect implicit or explicit

216 learning mechanisms continues to be debated (Clegg, DiGirolamo, & Keele, 1998; Goschke,

217 1998). Participants are instructed to make a button press response to one of four spatially

218 compatible target stimuli as quickly and accurately as possible. Unknown to the participants,

219 the presentation of the target stimuli will on occasions follow a repeating rather than a

220 random sequence.

₂₂₁   ***Protocol.***   The SRT was adapted from Nissen & Bullemer (1987). Four square

₂₂₂ placeholders were presented across the horizontal meridian. A red circle [RGB: 255, 0, 0]

₂₂₃ appeared in one of the 4 squares for 500 ms. This served as the target stimulus. Participants

₂₂₄ responded by pressing the finger of their dominant hand that spatially aligned to the target

₂₂₅ circle, using the relevant 'j', 'k', 'l' or ';' keys. The subsequent target stimulus appeared 500

₂₂₆ ms after a correct response had been made. Participants completed 4 blocks of 100 trials.

₂₂₇ For blocks 1 and 4, the location of the target stimulus for each trial was randomly selected

₂₂₈ from a uniform distribution. These blocks are referred to as 'Random'. For blocks 2 and 3, a

₂₂₉ repeating sequence of 10 elements was used to determine the target location. The sequence

₂₃₀ was repeated 10 times. The repeating sequence was 4-2-3-1-3-2-4-2-3-1, with 1 being the

₂₃₁ leftmost placeholder, and 4 being the rightmost placeholder. These blocks are referred to as

₂₃₂ 'Sequence' blocks. Learning in the SRT is tested by comparing mean RTs between Sequence

₂₃₃ and Repeat blocks in the latter half of the experiment (block 4 vs 3).

₂₃₄   **Contextual Cueing (CC).**   CC tasks tap how the visual system exploits statistical

₂₃₅ regularities to guide visual search (Sisk, Remington and Jiang, (2019); Jiang and Sisk

₂₃₆ (2020)). Participants are typically asked to report the orientation of a rotated 'T' target

₂₃₇ presented among an array of distractor 'L's. Participants are not informed that a set of the

₂₃₈ displays are repeated throughout the course of the experiment, while the remaining displays

₂₃₉ are novel to each trial. Typically RTs to the repeat displays become faster than novel

₂₄₀ displays throughout the course of the experiment (e.g. Chun & Jiang, 1998; Nydam, Sewell,

₂₄₁ & Dux, 2018). Participants are typically poor at recognising repeat displays in a subsequent

₂₄₂ recognition test (Sisk, Remington and Jiang, (2019); Jiang and Sisk (2020)), which has

₂₄₃ prompted the conclusion that CC reflects a process of implicit learning (but see Vadillo,

₂₄₄ Konstantinidis, & Shanks, 2016; Vadillo, Linssen, Orgaz, Parsons, & Shanks, 2020; Vadillo,

₂₄₅ Malejka, Lee, Dienes, & Shanks, 2021).

₂₄₆   ***Protocol.***   The CC protocol was the same as that reported by Nydam et al (2018)

₂₄₇ which is modeled on Chun and Jiang (1998). Each trial began with a white fixation cross

248   presented on a grey screen [RGB: 80, 80, 80]. An array of 12 L's and a single T were then

249   presented presented within an invisible 15 x 15 grid that subtended 10° x 10° of visual angle.

250   Orientation of each L was determined randomly to be rotated 0°, 90°, 180° or 270° clockwise.

251   The T was oriented to either 90° or 270°. Participants reported whether the T was oriented

252   to the left (using the 'z' key) or the right (using the 'm' key), as quickly and accurately as

253   possible. The task consisted of 12 blocks of 24 trials. For half the trials in each block, the

254   display was taken (without replacement) from 1 of 12 configurations that was uniquely

255   generated for each participant, where the location of the distractors and target (but not the

256   orientation of the target) was fixed. These trials were called 'repeats'. For the remaining

257   trials, the display was randomly generated for each trial, making them 'novel'. Displays were

258   generated with the constraint that equal items be placed in each quadrant and each

259   eccentricity. Target positions were matched between the repeat and novel displays for both

260   quadrant and eccentricity. The exact location of the item was jittered within each cell for

261   each presentation, to prevent perceptual learning or adaptation to the specific position of the

262   item. The order of display type (repeat vs novel), configuration (1:12) and target orientation

263   (left or right) was randomised for each block. Mean RTs to each block (1:12) and display

264   type (repeat vs novel) were taken as the dependent variable.

Statistical Approach

266   All the data and code used for the current analyses are available online. All data were

267   analysed using R (2015) and RStudio (RStudio Team, 2020). The analysis of the data from

268   each task followed two steps; first, to ascertain that we observed the typical findings for each

269   of the paradigms, we applied the relevant conventional statistical model to the full dataset

270   (N=313). Next, we implemented a simulation procedure to determine the effect sizes and

271   p-values that would be attained over many experiments conducted at multiple levels of

272   sample size.

273 **Simulation procedure.**   For each paradigm, we simulated experiments across 20

274 different sample sizes (N), defined on a logarithmic interval between N_{13} and N_{313} ($N = [13,$

275 15, 18, 21, 25, 30, 36, 42, 50, 59, 69, 82, 97, 115, 136, 160, 189, 224, 265, 313]). We opted for

276 a logarithmic interval given that changes in effect size variability should be greater across

277 changes of N when N is lower, relative to when Ns are higher. To simulate $k=1000$

278 experiments at each of our chosen N, we sampled N participants from N_{max} (N_{313}) over k

279 iterations. The relevant analysis was applied to each of the samples. Details regarding which

280 analyses were applied to each k sample are listed below for each paradigm. Sampling with

281 replacement ensured that the samples carried the Markov property. One potential concern is

282 that any reductions in observed effect size variability may be attributable to saturation as

283 the simulated N approaches the maximum (N_{313}), rather than a genuine reduction in

284 variance of the estimate of the effect. Specifically, it could be that as N approaches 313, the

285 overlap of participants between samples is greater than when N equals a lower number such

286 as 13. It follows then that any decreasing variability in effect size estimates at higher Ns

287 could be due to the decrease in variability of the samples, rather than the improved estimate

288 of the population variance that should come with a larger N. We have run simulations that

289 argue against this explanation (see appendix i).

290 **Effect Sizes.**   For each paradigm, we report the following information from the

291 simulated effect size distributions; first we used simulations using N_{313} to provide a best

292 estimate of the effect size distribution. We therefore report, for each paradigm, the mean

293 (M), median (Mdn: when different to the M), standard deviation (SD), the .025 (lower

294 bound, LB) and .975 (upper bound, UB) quantiles. These values can be used to define, *a*

295 *priori*, the range of anticipated effect sizes for future experiments, and consequently, can be

296 used to inform study design.

297 We next determined to what extent using an N that is typical for the field impacts the

298 effect size distribution. We report the same summary statistics as above, from the simulation

299 using the N that is closest to the typical N for that task (N_{med}). To identify the typical N,

300 we conducted a survey of the recent literature and computed the median N for each

301 paradigm (see below). We next computed the *precision loss* incurred from using N_{med} by

302 taking the ratio of the difference between the LB and UB quantiles for N_{med} and N_{313}:

$$qq\text{-}ratio = \frac{UB_{N_{med}} - LB_{N_{med}}}{UB_{N_{313}} - LB_{N_{313}}}$$

303 We refer to this measure from now as the qq-ratio. The qq-ratio indicates how under-

304 or over-inflated effect size estimates may be - a qq-ratio of 2 would suggest that effect sizes

305 may be twice as low or high as the LB or UB of the best estimate. For each task, we also

306 report the largest observed qq-ratio and the N for which the qq-ratio reaches less than

307 double. Note that although we expect qq-ratios to decrease as some function of $\frac{1}{N}$ (given

308 that variance depends on this term), the exact relationship between N and precision loss will

309 be dependent on population variance and measurement error for any given paradigm. We

310 also present qq-ratios across all N's, to provide an idea of potential precision gains from

311 increasing sample size.

312 Next we computed estimates regarding the extent to which precision loss in effect size

313 estimates may lead a researcher awry during study planning. To determine how often

314 sampling one or two similar studies with N_{med} may induce biases in power calculations, we

315 computed for each task and N, the proportion of simulated observations that fell within the

316 LB and UB quantiles of the best estimate (N_{313}). This provides the probability that

317 sampling one study will provide an accurate estimate of the true effect size. We refer to this

318 as the probability of attaining a hit, given the sample size ($p(\text{hit}|N_x)$). (As above, although

319 we expect this to change as a function of $\frac{1}{N}$, the exact relationship is dependent on

320 measurement noise). We next estimate effect size biases that result from aggregating across

321 experiments with statistically significant results ($p<.05$), under the assumption that the

322 published literature is more likely to only contain significant findings. We computed the

323 difference between the mean effect size from significant results and the mean effect size from

324 all results, and refer to this value as the *inflation bias*. Effectively, this analysis is assessing

325 the severity of the file-drawer effect for different sizes of N. To inform understanding of

326 potential file-drawer effects, we also report the proportion of studies that rejected the null

327 hypothesis ($p < .05$) for N_{med}, and the N where this value reached 90% (note: this is related

328 to the observed effect size, but we report it here for clarity).

329 Last, we sought metrics that may inform whether an experiment has yielded an

330 imprecise effect size estimate. Effect sizes are a function of the variability of the effect across

331 individuals, as well as intra-individual variability over trials (Rouder & Haaf, 2018). If either

332 of these stem from a non-normal distribution, mean and standard deviation estimates - and

333 consequently effect size computations - may be impacted. We thus determined whether the

334 skewness and kurtosis of this data could predict error in effect size estimates.

335 Error in effect sizes were defined for each task as the difference between the expected

336 value for N_{313} and each observed effect size from N_{med}. To attain predictors for each N_{med}

337 simulation, we calculated the key behavioural effect for each participant (in raw units) and

338 computed the Pearson's skewness and kurtosis coefficients of the resulting distribution of

339 effects. We also computed the variability, skew and kurtosis from each participant's

340 performance across trials, and took the means of these measures across participants. The

341 resulting variables (effect skewness, effect kurtosis, mean intra-individual variance, skewness,

342 and kurtosis) served as predictors in a multiple regression analysis, using effect size error as

343 the criterion variable. If any of the regressors themselves showed high levels of skew then a

344 log transformation was applied. All model residuals were checked for homoscedasticity. Note

345 that although we present the full models below, performing stepwise regression yielded the

346 same pattern of results.

347 To protect against interpreting over-fitted models, we performed k-fold cross-validation

348 for each multiple regression model, where k=10, and we report the mean r^2_{cv} (and standard

349 deviation) across folds. Next, we determined which regressors consistently predicted effect

350 size error across the four tasks. We then sought to identify which values of such predictors

351 suggest a problematic effect size error (defined as effect size errors that were less or more

352 than the .025 and .975 quantiles for N_{313}). We achieved this using simple regression, as we

353 sought to simulate how much variability may be accounted for when a researcher uses a

354 single piece of information to estimate effect size imprecision.

355 ***Computing Effect Sizes.*** To compute effect sizes for the paradigms analysed using

356 a repeated-measures ANOVA (AB, MT and CC), we computed partial epsilon squared (ϵ_p^2),

357 as this measure is unbiased, unlike η_p^2 (Okada, 2013). (Indeed, an earlier version of our

358 manuscript showed that η_p^2 estimates are biased on average, even for sample sizes of N=313,

359 [1]). We use the formula for ϵ_p^2 as defined in (Carroll & Nordholm, 1975, eq 11):

$$\epsilon_p^2 = \frac{F - 1}{F + \frac{df_w}{df_b}} \tag{1}$$

360 where F is the F statistic for the effect, df_w is the degrees of freedom within groups,

361 and df_b is the degrees of freedom between groups. The SRT paradigm instead uses a

362 paired-samples design. For this paradigm we computed Cohen's d_z (see Lakens (2013), eq 6):

$$d_z = \frac{M_{\text{diff}}}{\sqrt{\frac{\sum(X_{\text{diff}} - M_{\text{diff}})^2}{N-1}}} \tag{2}$$

363 where M_{diff} is the mean difference between groups, and X_{diff} is the difference score

364 for one subject.

365 To facilitate our interpretation of effect sizes as small, medium or large, we refer to

366 Cohen (1992) for ϵ_p^2 and to Gignac & Szodorai, (2016) for d_z.

for drawing our attention to this

367 ***Representative N.*** To attain an *N* that reflects what is commonly used for each

368 paradigm, we surveyed the three most relevant *Journal of Experimental Psychology* journals

369 (*General, Human Perception & Performance* and *Learning, Memory & Cognition*) for all

370 articles mentioning use of any of the current paradigms. We searched back for a total of 60

371 experiments or back from today to 2005, whichever occurred first. We then computed the

372 median sample size used across all experiments found from the survey. The results from the

373 survey are presented in Table 1.

374 **Analysis of Experimental Tasks.**

375 ***Attentional Blink.*** As is typical for the field, and to ascertain the effectiveness of

376 the lag manipulation, T2|T1 accuracy was subject to a repeated measures ANOVA, with lag

377 (2, 3, 5, & 7) as the independent variable. This analysis was also applied to each *k* sample.

378 For each *k* sample, ϵ_p^2 and the resulting *p* value were taken for the main effect of lag. For this

379 task, and all remaining ANOVA tests, models were fit using the *anova_test()* function from

380 the *rstatix* package. Where possible, the models were fit using type 3 sum of squares, owing

381 to the computational expediency and match to commercial statistical software packages. In

382 some cases, models were unable to be fit using type 3 sum of squares, owing to rank

383 deficiencies in the underlying design matrix (e.g. when one participant was drawn more than

384 twice within a sample). In these cases, models were fit using type 1 sum of squares. However,

385 as the experiment designs were fully balanced, each sum of squares type should yield the

386 same results.

387 ***Multitasking.*** To ascertain the effectiveness of the multitasking manipulation, the

388 data were modelled using a 2 (task-modality: visual-manual vs auditory-manual) x 2 (task:

389 ST vs MT) repeated-measures ANOVA. This analysis was also applied to each *k* sample; ϵ_p^2

390 and *p* are reported for both the main effect of task and the task-modality x task interaction.

391 ***Serial Response Task.*** To ascertain whether participants learned the repeating

392 sequences, RTs in the final block of sequence trials (block 3) were compared to those in the

393 final block of random trials (block 4) using a paired-samples t-test. This analysis was also

394 applied to each k sample, and we present the resulting Cohen's d_z, and p value from each

395 test.

396   ***Contextual Cueing.*** To ascertain whether participants became faster for repeat

397 relative to novel trials over the course of the experiment (i.e. whether participants learned

398 the statistical regularities of the repeated displays), the data were subject to a block (1:12) x

399 condition (repeat vs novel display) repeated measures ANOVA. Specifically, learning should

400 be evidenced by a significant block x condition interaction. This analysis was applied to each

401 k sample, and we report ϵ_p^2 and p for the block x condition interaction.

402   As some studies from the contextual cueing literature suggest that the effect is better

403 characterised by a main effect of condition thereby implying rapid learning of the statistical

404 regularities (e.g. Peterson & Kramer, 2001; Travis, Mattingley, & Dux, 2013), we also report

405 the ϵ_p^2 and p for the main effect of condition.

Results

407   We first present the results from the standard analyses used for each task, to show that

408 we replicate the classic findings from each task. The key behavioural data are presented in

409 Figure 2.

Behavioural Results

411   **Attentional Blink.** The AB data are presented in Figure 2A. Accuracy for T2|T1

412 was lower for early relative to late lags; accuracy for T2|T1 decreased (by around p = 0.32)

413 when T2 was presented at lag 2, relative to lag 7. A one-way ANOVA revealed that the

414 effect of lag was statistically significant (F (2.4, 749) = 508, ϵ_p^2 = 0.62, p = 1.88e-157).

415 Post-hoc t-tests showed that accuracy at each lag differed statistically from accuracy at each

416 of the other lags (all p's $\leq$ 3.68e-18). Therefore, the AB paradigm yielded the typically

417 observed effects.

418 **Multitasking.**   As anticipated, RTs were slowed for multitask relative to single task

419 conditions (see Figure 2B). Mean RTs were on average 0.31 (95% CI[0.30, 0.33]) seconds (s)

420 slower on MT trials (F(1, 312) = 2653, $\epsilon_p^2 = 0.89$, p<.0001). There was also a significant

421 task modality (sound or visual) x task (ST vs MT) interaction (F(1, 312) = 59.4, $\epsilon_p^2 = 0.16$,

422 p<.0001). The MT cost (MT RT - ST RT) was larger for the sound task relative to the

423 visual task by on average 0.08 s (95% CI[0.06, 0.10]). This latter finding has been reported

424 previously (Hazeltine & Ruthruff, 2006). We continue to interrogate this effect, as it serves

425 as an example of an interaction with a small effect size. This facilitates comparisons to the

426 contextual cueing task, as reported below.

427 **SRT.**   The results from the SRT paradigm are presented in Figure 2C. Participants

428 learned the repeating sequence; RTs were on average 0.049 s faster (95% CI [0.046, 0.051])

429 for the sequence relative to the random condition (t(312) = 33.60, $d_z = 1.90$, p = 1.13e-105).

430 **Contextual Cueing.**   Participants learned the repeat displays over blocks (see Figure

431 2D); the RT data showed a significant albeit small block x condition interaction (F (10.12,

432 3158.9) = 4.80, $\epsilon_p^2 = 0.01$, p = 6.01e-07). There was no statistically significant difference

433 between RTs for repeat and novel displays for block 1: (t (312) = 0.53, p = 0.60, μ difference

434 = 0.01 s, sd: 0.20). However, by block 12, RTs for repeat displays were on average 0.04 s

435 faster than novel displays (sd: 0.14, t (312) = 5.33, p = 1.87e-07. There was also a significant

436 and larger main effect of block (F(5.03, 1567.97) = 131.08, $\epsilon_p^2 = 0.29$, p = 1.07e-116). and a

437 significant main effect of condition (F(1.00, 312.00) = 32.78, $\epsilon_p^2 = 0.09$, p = 2.42e-08).

438 **Effect Sizes**

439 **Summary Statistics and Precision Loss.**   Across tasks, we observed a range of

440 small to large effect sizes ($epsilon_p^2$: .01 -.9), thus we are able to characterize the extent of

441 precision loss across a range of effect size scenarios. For studies run with N_{med}, the range of

442 precision losses we observed was 1.78 - 4.16, suggesting that caution is warranted when

443 basing power calculations on the outcomes of a small number of studies. The N required to

444 reduce precision loss to < 2 ranged from 36 - 82. For both the interaction effects currently

445 studied (MT and CC), the effect size distributions for N_{med} spanned from below to above

446 zero, suggesting that differing conclusions may be reached across studies. Specifically, when

447 the effect size is less than zero, the direction of the effect has the opposite sign. The observed

448 power to reject the null hypothesis ranged from p=.35 - 1, suggesting areas where there may

449 be missing literature owing to publication bias. We next report these details for each task.

450   ***Attentional Blink.*** The AB effect was large (see Figure 3A); N_{313} ϵ_p^2 $M = 0.62$

451 (*SD*: 0.03, *LB*: 0.57, *UB*: 0.67). The simulated effect sizes for N_{med} (N_{25}) produced the same

452 mean effect size estimate (*M*: 0.62, *SD*: 0.06, *LB*: 0.48, *UB*: 0.74, see Figure 3B). With

453 regard to extent of precision loss; the qq-ratio for N_{med} was 2.38. The qq-ratio for small N

454 was ~3 ($N_{13} = 3.06$, $N_{15} = 2.98$), and reached < 2 at N_{42} ($N_{36} = 2.09$, $N_{42} = 1.81$). The

455 remaining qq-ratios are presented in Figure 5.

456   Across all N, the probability of rejecting the null hypothesis was 1.

457   ***Multitasking.***

458   *Main effect of task condition.* For the MT paradigm, the main effect of task condition

459 was large (N_{313} ϵ_p^2 $M = 0.90$, *SD*: 0.01, *LB*: 0.87, *UB*: 0.92), and the simulated effect sizes

460 for N_{med} (N_{42}) produced the same mean effect size estimate (*M*: 0.90, *SD*: 0.03, *LB*: 0.84,

461 *UB*: 0.94, see Figure 3D). With regard to precision loss, the qq-ratio for N_{med} was 1.89.

462 Comparable to the AB, qq-ratio for small N was ~3 ($N_{13} = 2.97$, $N_{15} = 3.03$), and was < 2

463 for N_{36} ($N_{30} = 2.12$, $N_{36} = 1.96$). The remaining qq-ratios are presented in Figure 5.

464   Across all N, the probability of rejecting the null hypothesis was 1.

465   *Task condition by modality interaction.* The task condition x modality interaction

466 achieved a medium effect size (N_{313} ϵ_p^2 $M = 0.17$, *SD*: 0.06, *LB*: 0.06, *UB*: 0.30, see Figure

467 3E), and the simulated effect sizes for N_{med} produced the same mean effect size estimate (M:

468 0.17, *Mdn*: 0.16, *SD*: 0.12). However, the *LB* and *UB* quantiles from N_{med} crossed zero (*LB*:

469 -0.02, *UB*: 0.43, see Figure 3F), suggesting that using N_{med} will sometimes produce differing

470 inferences with regard to the effect size, compared to N_{313}. With regard to precision loss, the

471 qq-ratio for N_{med} was 1.78. The qq-ratio for small N was ~2.75 (N_{13} = 2.88, N_{15} = 2.72),

472 and reached < 2 at N_{36} (N_{30} = 2.00, N_{36} = 1.87). The remaining qq-ratios are presented in

473 Figure 5.

474   The probability of rejecting the null hypothesis at N_{med} was 0.79. A sample size of N_{82}

475 was required to achieve statistical power of > 90 % (N_{69} p = 0.90, N_{82} p = 0.95).

476   ***Serial Response Task.***   For the SRT, the effect of sequence vs random was large

477 (N_{313} d_z M: 1.93, *SD*: 0.21, *LB*: 1.53, *UB*: 2.33, Figure 4A). Here, there was disagreement

478 between N_{313} and N_{med} (N_{36}) regarding the means of the simulated effect size distributions

479 (N_{med} d_z M = 2.02, *SD*: 0.44, *LB*: 1.22, *UB*: 2.86, see Figure 4B). With regard to precision

480 loss, the qq-ratio for N_{med} was 2.05. The remaining qq-ratios are presented in Figure 5. The

481 qq-ratio for small N was ~3.5 (N_{13} = 3.62, N_{15} = 3.35), and reached under 2 at N_{42} (N_{36} =

482 2.05, N_{42} = 1.88).

483   Across all sampled N, the probability of rejecting the null hypothesis was 1.

484   ***Contextual Cueing.***

485   *Block x Condition Interaction.*   The block x condition interaction effect was on the

486 boundary between very small and small (N_{313} ϵ_p^2 M: 0.02, *SD*: 0.01, *LB*: 0.01, *UB*: 0.04,

487 Figure 4C). There was a minor discrepancy between the N_{313} and N_{med} (N_{25}) means, but

488 the N_{med} *Mdn* agreed (M: 0.03, *Mdn*: 0.02, *SD*: 0.03). Similar to the SRT task, the effect

489 size distribution for N_{med} included zero (N_{med} *LB*: -0.02, *UB*: 0.11), thus experiments with

490 N_{med} may sometimes motivate different conclusions to N_{313}. Specifically, when the effect size

491 is below zero, it would be concluded that repeating displays leads to a slowing of RTs (rather

492 than speeding RTs), relative to novel displays. There was also a greater extent of precision

loss at N_{med} than was observed for other tasks (qq-ratio: 4.16). The qq-ratio for small N was ~6 ($N_{13} = 6.41$, $N_{15} = 5.64$), and reached under 2 at N_{82} ($N_{69} = 2.08$, $N_{82} = 1.84$). The remaining qq-ratios are presented in Figure 5.

The probability of rejecting the null hypothesis at N_{med} was $p = 0.35$. A sample size of N_{82} was required to achieve statistical power of > 90 % (N_{69} $p = 0.90$, N_{82} $p = 0.95$).

Main Effect of Condition. The main effect of condition was large (N_{313} ϵ_p^2 M: 0.31, SD: 0.03, LB: 0.25, UB: 0.37, see Figure 4E). There was a minor discrepancy between the mean estimates for N_{313} and N_{med} (M: 0.33, Mdn: 0.32, SD: 0.08, LB: 0.20, UB: 0.47, see Figure 4F). Precision loss was comparable to the SRT (qq-ratio: 2.19). The qq-ratio for small N was ~2.8 ($N_{13} = 2.82$, $N_{15} = 2.75$), and reached under 2 at N_{36} ($N_{30} = 2.19$, $N_{36} = 1.97$). The remaining qq-ratios are presented in Figure 5.

The probability of rejecting the null hypothesis at N_{med} was $p = 0.39$. A sample size of N_{136} was required to achieve statistical power of > 90 % (N_{115} $p = 0.97$, N_{136} $p = 0.99$).

Impacts of imprecision and missing literature. Having characterized the effect size distributions for each task, we next sought to determine the impact of effect size imprecision when basing power calculations on a similar study that uses N_{med}, and the extent to which effect size estimates could be inflated in cases where there may be missing information owing to publication bias. For the former, we computed p(hit$|N$); for the AB, MT and SRT paradigms, the p(hit$|N_{med}$) was ~0.66 (AB: 0.65, MT tc: 0.67, MT tc x m: 0.67, SRT: 0.65). This suggests that sampling a similar study will produce a reasonable *a priori* effect size estimate 2/3 of the time (Note: it is interesting that the AB, MT and SRT fields appear to have converged on an N_{med} that puts them on a comparable footing for hitting the best effect size. Indeed, if the MT and SRT fields used the same sample size as the AB field, the p(hit$|N_{25}$) ratios for the three effects would be ~0.57 (MT tc: 0.59, MT tc x m: 0.54, SRT: 0.57)). For the CC paradigm, the p(hit$|N_{med} = $ ~.48 (b x c: 0.40, c: 0.55). This suggests that basing effect size estimates on a similar CC study will result in an

519 appropriately powered study 50% of the time. The remaining p(hit$|N_x$) are presented in

520 Figure 6.

521   Next, we estimate the *inflation bias* that is incurred by using a given N. Here we focus

522 on the MT and CC paradigms, as they contained effects where the null was not consistently

523 rejected at N_{med}. For the MT task, the task condition x modality inflation bias for N_{med} was

524 0.04 ϵ_p^2. No inflation bias was present for the main effect of task condition (all $N = 0$). For

525 the CC, the block x condition interaction inflation bias at N_{med} was 0.03 ϵ_p^2, for the main

526 effect of condition the N_{med} inflation bias was nominal (-0.003 ϵ_p^2). These and the remaining

527 inflation bias estimates are presented in Figure 7.

528   **Predicting error in effect size estimates.**   Last, we determined which aspects of

529 the data were predictive of erroneous effect size estimates. Multiple-regression analysis

530 showed that between 9-40% of the variance in effect size errors were predicted by effect

531 skewness, effect kurtosis, mean intra-individual variance, mean intra-individual skewness,

532 and mean intra-individual kurtosis (M r_{cv}^2s (SD): AB: 0.39 (0.08), MT main effect of task:

533 0.09, (0.05), MT task x modality interaction: 0.11 (0.04), SRT: 0.22 (0.09), CC main effect

534 of condition: 0.19 (0.08), all model ps $< .001$), apart from for the block x condition effect

535 from the CC task, where the model accounted for a negligible proportion (1%) of effect size

536 error (F(5,994) = 2.35 , p = .04). This suggests that both inter- and intra-individual

537 skewness and kurtosis predict variability in effect size errors.

538   The resulting regression equations (see appendix ii) are useful for researchers using the

539 tasks studied here, who wish to predict the extent to which their own experiment may have

540 yielded an imprecise effect size estimate. However, what is more widely useful is

541 understanding which regressors significantly predict effect size imprecision across tasks. We

542 therefore determined which regressors showed significant predictive power across tasks,

543 applying Bonferronni correction for multiple comparisons. For the AB, MT, and SRT tasks,

544 effect skewness and kurtosis were significant predictors of effect size error (all ps $<= .005$,

545 see appendix ii). Mean intra-individual skew was a significant predictor across all four tasks

546 (all ps < .008), apart from for the MT task x condition interaction (p=.08).

547   Having identified the regressors that suggest imprecision in effect size estimates across

548 tasks, we next sought to determine which predictors could be used as a marker of

549 imprecision when a researcher is unable to hold the influence of other predictors constant.

550 Such a finding would suggest that use of a single piece of information (e.g. effect skewness)

551 could act as a marker for whether a single experiment has yielded an imprecise effect size

552 estimate. Simple regressions between each predictor and effect size errors showed that effect

553 skewness tended to predict a higher proportion of the variance (Adjusted R^2 s: 0.04 - 0.10,

554 all ps < .001) than kurtosis (Adjusted R^2: -0.00 - 0.01, all ps < .7), apart from for the MT

555 condition x task interaction (skewness: Adjusted R^2 : 0.0004 p<.01, kurtosis: Adjusted R^2 :

556 0.06 p<.001). Although mean within-participant skewness predicted higher amounts of error

557 variance for the AB (Adjusted R^2: 0.18) and CC main effect of condition (Adjusted R^2:

558 0.16), its predictive power was poor for the remaining tasks (Adjusted R^2 s: <= .02, all ps

559 < .17). This suggests that effect skewness is the best potential general proxy of effect size

560 imprecision, when not controlling for other influences.

561   As effect skewness is the best candidate for predicting variance in effect size error

562 across tasks, we next determined which values of effect skewness predict problematic levels of

563 effect size error (defined as values falling outside the .025 and .075 quantiles for N_{313}).

564 Across tasks, moderate to large negative effect skewness (-0.70 - -1.29) predicted erroneous

565 over-estimates of effect size, whereas large positive effect skewness (1.35 - 3.80) predicted

566 erroneous under-estimates. Thus, if data from a single experiment shows moderate to large

567 values of effect skewness, this is a signal that extra caution is warranted when interpreting

568 effect size estimates.

⁵⁶⁹ <center>**Discussion**</center>

⁵⁷⁰   We simulated 1000 bootstrapped experiments across 20 Ns ranging from 13 to 313.

⁵⁷¹ For each paradigm and from each set of simulations, we determined the impact of N on error

⁵⁷² in effect size estimates. In doing so, we were able to quantify a range of effect sizes that

⁵⁷³ researchers can consider when performing power analyses, particularly when using the AB,

⁵⁷⁴ MT, SRT or CC paradigms. We determined precision loss in effect size estimates as a

⁵⁷⁵ function of N and found that decreasing N_{max} to N_{med} inflated the range of effect sizes by

⁵⁷⁶ factors ranging between 1.78-4.16. We also computed the probability of attaining an accurate

⁵⁷⁷ effect size estimate (defined as falling between the .025 and .975 quantiles of N_{max}), and

⁵⁷⁸ found that sampling a single study would result in a reasonable estimate on between 40-67%

⁵⁷⁹ of samples. Last we computed the inflation bias for effects that carried less than 90% power

⁵⁸⁰ at N_{med}. We found that inflation biases ranged from a nominal to small effect (ϵ_p^2: -.003-.03).

⁵⁸¹ These findings can inform study planning, study interpretation and theory development.

⁵⁸²   **Study Planning.**   Our findings have practical relevance for study planning. First, we

⁵⁸³ have provided a range of effect sizes that researchers can use to inform power calculations for

⁵⁸⁴ their own studies. Furthermore, we have shown that in the case of smaller effects (ϵ_p^2 :

⁵⁸⁵ 0.01-0.3), N_{med} was consistently smaller than is required to attain 90% power to reject the

⁵⁸⁶ null hypothesis. This suggests that researchers should consider whether their research

⁵⁸⁷ question concerns an effect that may be subtle or variable across participants, and if so,

⁵⁸⁸ recruit higher Ns than is currently standard. This would promote maintenance of

⁵⁸⁹ appropriate type 2 error rates. For the small effects observed here, a minimum N of 69

⁵⁹⁰ participants was required. Note also that for each task, the statistical model used was one

⁵⁹¹ geared at ascertaining the existence of an effect (e.g. was there an AB present?). These

⁵⁹² findings suggest that as soon as hypotheses become more nuanced, for example, referring to

⁵⁹³ factors that should modulate the strength of a known effect, effect sizes are likely to be of a

⁵⁹⁴ smaller range.

⁵⁹⁵   The current findings also reveal that sampling a few similar studies to determine a

⁵⁹⁶ suitable minimum effect size for power analysis is a questionable approach, given the

⁵⁹⁷ standard N_{med}s. For larger effects, this will lead to an inappropriately powered study 33%

⁵⁹⁸ of the time, whereas this rate will be 50% for smaller effects. Furthermore, the current

⁵⁹⁹ inflation bias data suggest that in the case of interactions, (and smaller effects), a

⁶⁰⁰ comprehensive meta-analysis is likely to yield an inflated estimate when the field uses $< N_{69}$

⁶⁰¹ as standard. Therefore, researchers using existing research to determine appropriate effect

⁶⁰² sizes for power analyses would be well advised to adjust (decrease) anticipated minimum

⁶⁰³ effect sizes to ensure they avoid an underpowered study. However, given the suggested

⁶⁰⁴ currently indicated state of the field, the better approach is for researchers to use

⁶⁰⁵ theoretically motivated minimum effect size estimates, that include consideration for how

⁶⁰⁶ likely the effect is to vary across individuals, when conducting power calculations.

⁶⁰⁷   These findings complement the insights offered by previous simulation studies into the

⁶⁰⁸ factors influencing effect size estimates. Previous simulation work has highlighted conditions

⁶⁰⁹ that cause bias in effect size estimates (Gelman & Carlin, 2014; e.g. Lane & Dunlap, 1978;

⁶¹⁰ Okada, 2013; Troncoso Skidmore & Thompson, 2013) and the consequences for power

⁶¹¹ calculations (Albers & Lakens, 2018; Anderson, Kelley, & Maxwell, 2017), by generating

⁶¹² data-sets under simplifying conditions such as using between subjects designs or using lower

⁶¹³ and fewer samples of N. Collectively, these studies have determined which effect size

⁶¹⁴ measures provide unbiased estimates (e.g. ϵ_p^2 vs η_p^2), that effect size estimates are likely to be

⁶¹⁵ inflated due to publication bias and low statistical power, and that the process of study

⁶¹⁶ design should account for uncertainty in the magnitude and direction of anticipated effect

⁶¹⁷ sizes. However, it can be challenging to determine the uncertainty around effect size

⁶¹⁸ estimates and the impact of differing N on that uncertainty without quantifications of the

⁶¹⁹ expected effect size, and the variability around that effect size, for a given field of study. By

⁶²⁰ taking the current step away from simplifying data generating conditions, and instead

⁶²¹ simulating experiments based on data from specific paradigms with more complex designs,

we provide insight into the uncertainty regarding effect size estimates for ecologically valid data taken from the AB, MT, SRT and CC paradigms.

We also show that for the larger effect sizes studied here (ϵ_p^2:0.6-0.9, d 1.9), effect skewness, which is driven by inter-participant variability, shows a predictive relationship with imprecision in effect size estimates. This was not the case for the smallest effects under study (ϵ_p^2:0.02-0.31), where intra-individual skewness and kurtosis of the data were the significant predictors of imprecision. Thus, researchers wishing to determine the likelihood of an erroneous estimate in their own data should examine different features of the data (inter-vs intra-individual skewness) according to the expected effect size. This finding also carries potential consequences for the trade-off between N and repeated measures (number of trials) that must be decided for any given study. Specifically, when an effect size is small across participants, intra-individual variability is the limiting factor for precisely quantifying an effect. This accords with previous observations concerning the reduction of type 2 errors (Rouder & Haaf, 2018). What the current findings suggest is that decision processes regarding the trade-off between N and repeated measures should also consider the number of each required to attain a relatively normal distribution of effects, for either inter- or intra-individual data, depending on whether the anticipated effect size is large or small respectively. Future work should use simulation approaches to verify the causal link between skewness and error in effect size estimates.

Study Interpretation. Our findings also offer insight into the interpretation of existing studies using the AB, MT, SRT and CC paradigms. Researchers evaluating existing studies can use the current findings to estimate the potential imprecision of a given effect size, and can accordingly weight their belief in consequent theoretical assertions. The current findings also enable (largely positive) evaluations of the broader literature for each paradigm. Statistical power was largely very strong, apart from for interactions, which involved small or medium effects. This suggests that the published literature will likely cumulatively reflect a reasonable effect size estimate, across all N, when the effect under study is a main effect.

$_{649}$ However, for interaction effects (for which we only saw very small to medium effect sizes [ϵ_p^2:

$_{650}$ .02-.17]), we consistently found that ~82 participants were required to achieve > 90% power,

$_{651}$ which was far above the N_{med} for each paradigm. It follows that interactions would be

$_{652}$ relatively under-powered since data is being divided into more bins, and this accords with

$_{653}$ other observations that current practices result in low statistical power for interaction effects

$_{654}$ (e.g. Lakens & Caldwell, 2021). However, our survey of the field suggests that investigation

$_{655}$ of interaction effects with low N remains common practice when measuring attention,

$_{656}$ executive function and implicit learning. The current findings demonstrate that cumulative

$_{657}$ approaches would be hampered by current practices in characterizing interaction effects (at

$_{658}$ least in the case of MT and CC).

$_{659}$ We believe these findings offer new insights when considering what constitutes a well

$_{660}$ powered study for investigations into attention, executive function and implicit learning. The

$_{661}$ current findings show that achieving statistical power to reject the null hypothesis is either

$_{662}$ trivially easy, or, in the case of very small effects (as we observed for CC b x c), is inevitable

$_{663}$ with sufficient N. Therefore, demonstrating rejection of the null hypothesis has relatively

$_{664}$ little to offer if the goal is to develop theory and leverage insights from cumulative science

$_{665}$ (Chen et al., 2019; Cumming, 2014; Gelman & Carlin, 2014; Lorca-Puls et al., 2018). Here

$_{666}$ we show that if a given field can pool data, or collectively provide the appropriate simulation

$_{667}$ parameters, then it is possible to plan research studies with the aim of producing an effect

$_{668}$ size estimate that has an acceptable level of precision. Here we defined an acceptable level of

$_{669}$ precision as falling within the .025 and .975 quantiles of the distribution of the best

$_{670}$ estimate(N_{313}). The usefulness of our definition could potentially be limited to the current

$_{671}$ sample and task materials. It would be useful to conduct multiple large N studies aimed at

$_{672}$ characterising effect size distributions across multiple cognitive phenomena. This would not

$_{673}$ only inform tolerable precision levels, but could also help with theory development. For

$_{674}$ example, we would better understand the effect magnitude that candidate models should

$_{675}$ emulate. Further, there would exist more baseline effect magnitudes that could serve as a

reference, or upper limit, when hypothesising factors that modulate the effect.

Just as knowing about the distributional properties of effect sizes observed across many replications provides information about study design and interpretation, so too can considering the distributional qualities of observed p-values. The p-value is itself a random variable that will vary from experiment to experiment (e.g. Chen et al., 2019), yet this variation is rarely considered when researchers report a single p-value for each reported effect. Understanding exactly how a p-value may vary across replications can help identify where there may be missing literature owing to publication bias, or uncertainty regarding the rejection of the null hypothesis (e.g. Nolan, Vromen, Cheung, & Baumann, 2018). Moreover, although it is known that p-values are inversely related to effect size, the relationship is both non-linear and non-trivial to compute as it depends on other factors such as the sample size, the underlying data type (e.g. independent vs dependent) and the statistical test (Faul, Erdfelder, Lang, & Buchner, 2007). The current simulation approach could also be employed to better map the relationship between N and p-values, for varying effects. This can yield insights into uncertainty over p-values and assist with interpretation of research findings. We provide the p-value data from the current simulations as Supplemental figures [2] to help with this endeavor.

Theory Development.   The current simulation approach can also inform theory development. In the case of implicit learning, our results showed that for the CC paradigm, the block x condition interaction effect was very small (ϵ_p^2: .01-.04). This may be because the effect is very small across all variations of the paradigm, or that the current design parameters may not effectively measure the effect. The current paradigm was modeled on the seminal demonstration (Chun & Jiang, 1998). Nonetheless, there may be critical design parameters that with modification, elicit a larger (and more positive) range of interaction effects. Applying the current simulation approach to data collected across varying

---

[2] See https://github.com/kel-github/Super-Effects/tree/master/doc/supp-figs

701 implementations of the CC paradigm can yield insights into what produces the effect, and
702 consequently can help refine theory regarding the causes of the effect.

703   The current approach of using a large data-set also offers insight into the impact of
704 increasing individual variation while holding measurement error relatively constant, for each
705 paradigm under study here. Hopefully, at N_{313} the contribution of individual variation is
706 relatively low compared to the measurement error. Given this, the currently observed
707 comparable rates of change for the qq-ratio and p(hit$|N$) values across paradigms may be
708 unsurprising. This consistency may be of some value when quantifying the impact of
709 individual variation on predicted effect magnitudes. Furthermore, the range of effect sizes
710 observed for experiments at N_{313} provides an estimate of measurement error that could be
711 built into quantitative predictions for the AB, MT, SRT and CC effects.

712   **Limitations.**   It remains an open question whether the current findings generalize
713 beyond the paradigms and participant pool used here. There are some suggestions of
714 generalizability of the current observations across tasks that should be investigated in future
715 research. Across all the ϵ_p^2 findings, the standard deviations at N_{313} were small (*SD*s:
716 .01-.03), and each *SD* doubled or tripled as a function of moving from N_{313} to N_{med}.
717 Therefore, it is possible that effect sizes such as ϵ_p^2 will show a comparable reduction in
718 variability as N increases to the hundreds, across all paradigms. If this were found to be
719 true, then researchers could apply the rates of change observed here to effect size estimates
720 from their own field of study in order to determine the N required to achieve a tolerable level
721 of precision. Moreover, changes in p(hit$|N$) and qq-ratio rates were comparable across N for
722 all effects, regardless of size, suggesting invariance to the measurement differences across
723 paradigms. Future research should determine the extent to which these rates were dependent
724 upon the current sample of N_{313}, which was arguably homogeneous with regard to
725 population characteristics. Indeed, it is pertinent to determine the extent to which our
726 results would hold with more heterogeneous samples. For example, estimates of effect sizes
727 may be more variable under less constrained conditions, such as when community samples

728 complete online studies. Future work should determine the extent to which study design

729 choices may hamper precise effect size estimates in such groups.

730 A further limitation is that the p(hit$|N$) and qq-ratio values were dependent on the

731 range of effect sizes observed at N_{313}. The results may be different if we had sampled N_{1000}

732 (for example). Thus interpretation of the current findings is dependent on how willing the

733 researcher is to assume that several hundred participants is a sufficient representation of 'as

734 good as it gets'. Given the small ranges of effect sizes observed for N_{313}, we certainly think

735 this is a reasonable place to start.

Conclusions

737 By simulating experiments across varying N for popular paradigms from the study of

738 attention, executive function and implicit learning, we are able to provide insights into the

739 precision of effect size estimates that are unknowable from simulation approaches that make

740 simplifying assumptions regarding the data. Using the current approach, we can identify the

741 mean effect size and the variability of that effect size, under the best case scenario. This

742 allows us to quantify the change in precision of effect size estimates with varying N. We

743 identify that using a typical N can double imprecision of effect size estimates, and

744 characterize to what extent this reduces the chances that a single study will provide a

745 reasonable effect size estimate. In the case of the small effect sizes observed here, inflation

746 bias can amount to the equivalent of a small effect size. Amassing large data-sets to allow

747 characterisation of error in effect size estimates is a useful exercise when seeking to plan

748 studies that facilitate cumulative science.

Table 1

Typical N found from literature survey. n exp = number or experiments, med N = median N

| task	n exp	med N
AB	60	24
MT	60	40
CC	49	24
SRT	60	34

Figure 1. Task battery. A) Attentional Blink Paradigm (AB). Participants report the two letter targets from the rapid serial visual presentation of numbers and letters. B) Multitasking Paradigm (MT). Participants discriminate the colour of a disc, a complex tone, or both. C) Serial reaction time task (SRT). Participants respond to one of four stimuli, each mapped to a spatially-compatible button press. Unknown to participants, for half of the experimental blocks, the stimulus follows a repeating sequence. D) Contextual Cueing Paradigm (CC). i) Participants perform an inefficient visual search task where they search for a rotated T among L distractors. ii) Unknown to participants, half of the search arrays are repeated throughout the course of the experiment.
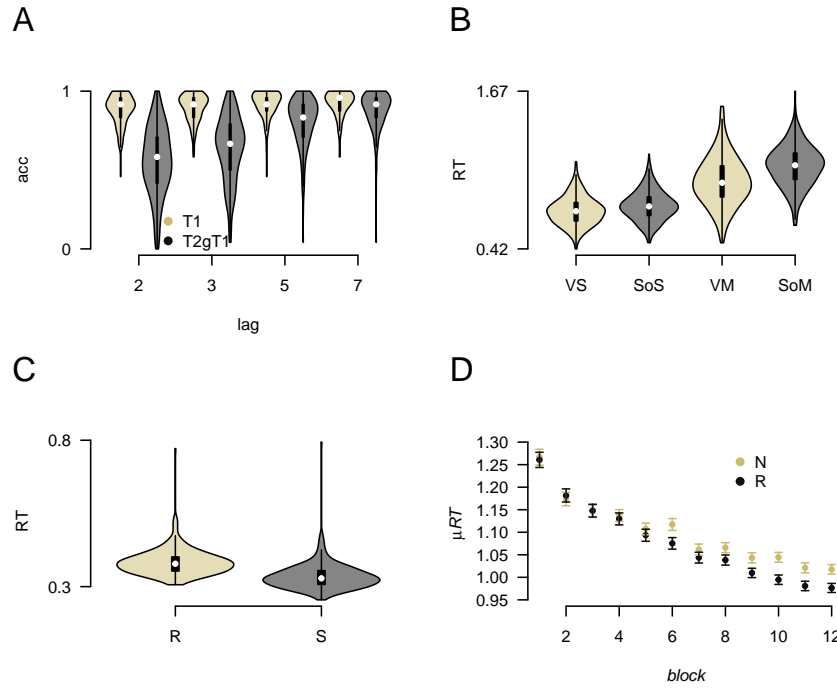

Figure 2. Behavioural Results. A) Attentional Blink Paradigm (AB). Accuracy (acc) for T2|T1 was lower at early lags, relative to later lags. Note that T1 accuracy is also plotted. B) Multitasking Paradigm (MT). RTs were slowed for multitask (M) conditions, relative to single-tasks (S). This difference was larger for sound tasks (So) than for visual (V) tasks. C) Serial Response Task (SRT). In the second half of the experiment, RTs were faster in the sequence (S) relative to the random (R) condition. D) Contextual Cueing (CC). RTs were faster for the repeat (R) than for the novel (N) displays, and this difference became larger throughout the course of the experiment.
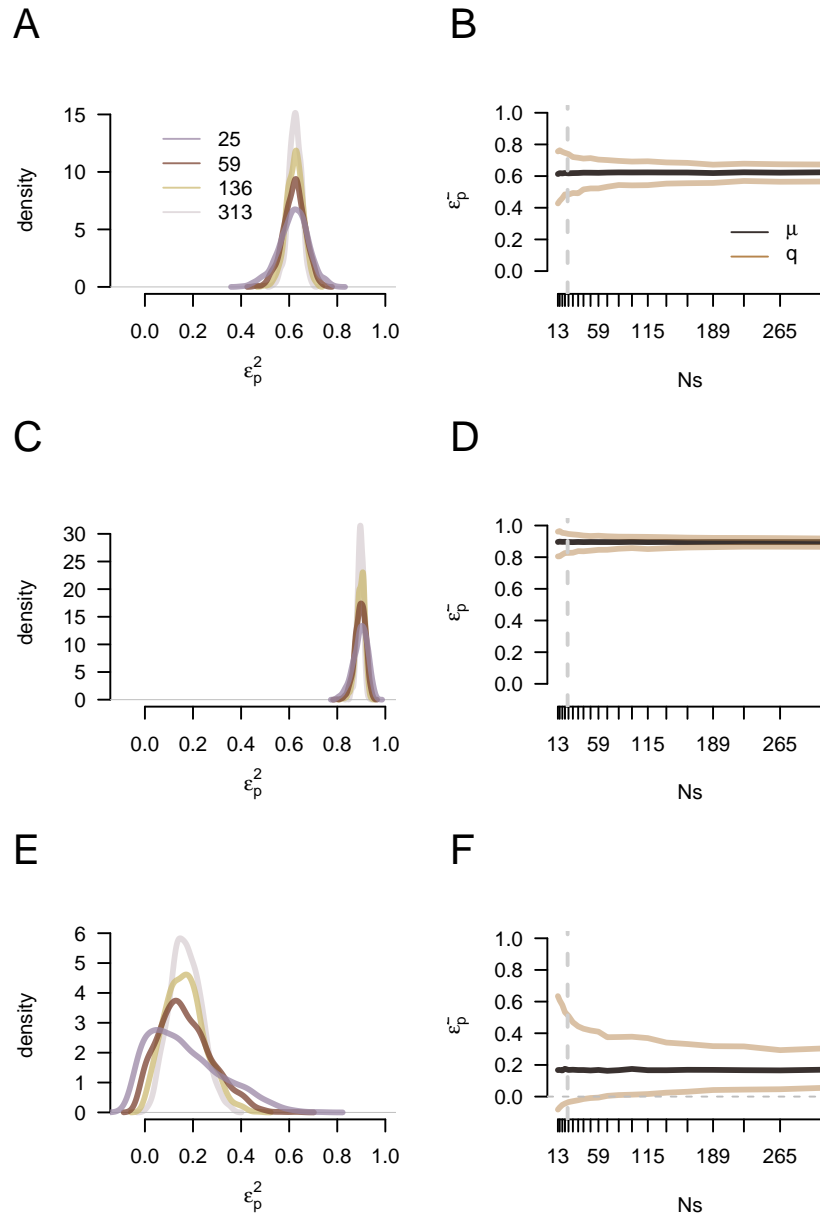

Figure 3. Effect size distributions for the AB and MT paradigms. A) AB: Partial epsilon sq

distributions for selected N for the main effect of lag. B) Showing the mean partial epsilon

squared, and the UB and LB quantiles [.025, .975], for the main effect of lag, across N (AB).

C) MT: Same as in A, but for the main effect of task condition (MT). D) Same as in B, for

the main effect of task condition (MT), E) As in C, but for the task x modality interaction

(MT), E) As D, but for the MT task x modality interaction
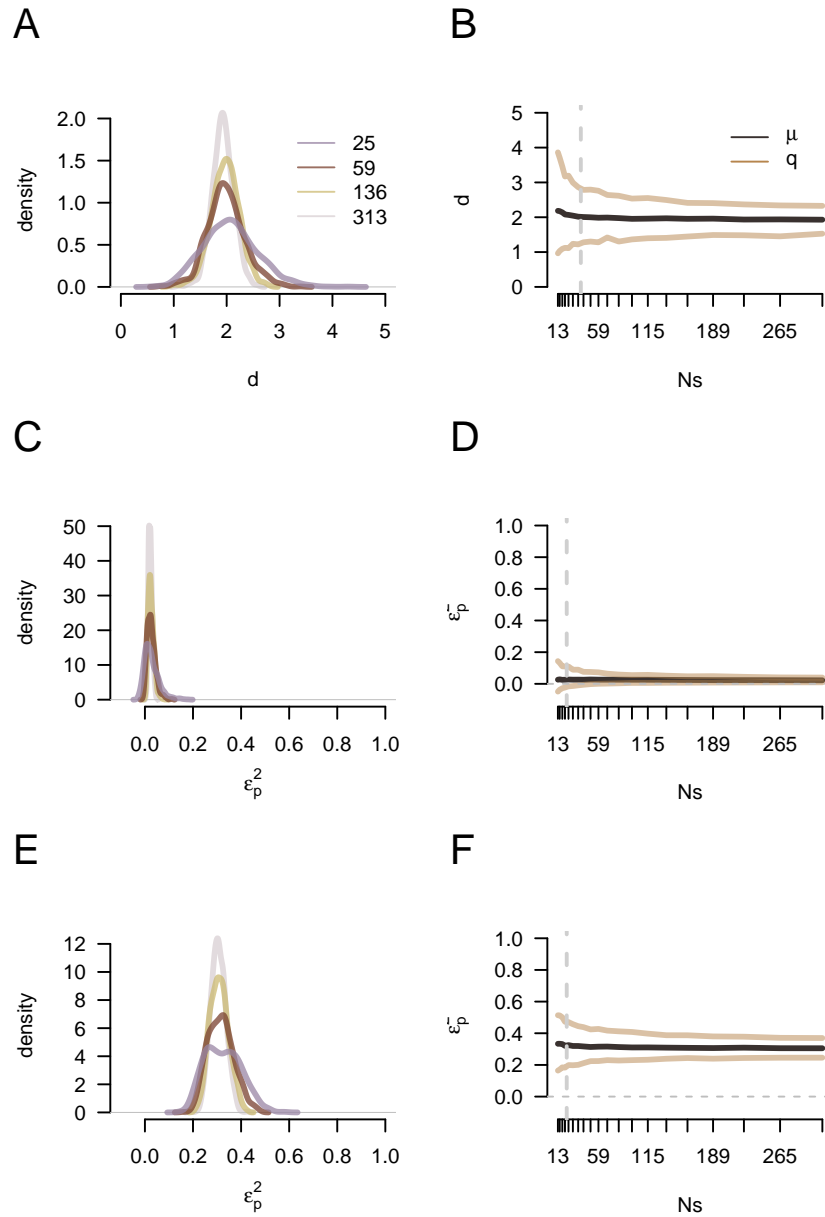

Figure 4. Effect size distributions observed for the SRT and CC paradigms. A) SRT: Cohens dz for the effect of sequence learning, for selected N. B) Showing the mean dz, and the UB and LB quantiles [.025, .975], for the effect of sequence, across N (SRT). C) CC: Same as in A, but for the block x condition interaction. D) Same as in B, for the block x condition interaction (CC), E) As in C, but for the main effect of condition (CC), E) As D, but for the main effect of condition (CC)
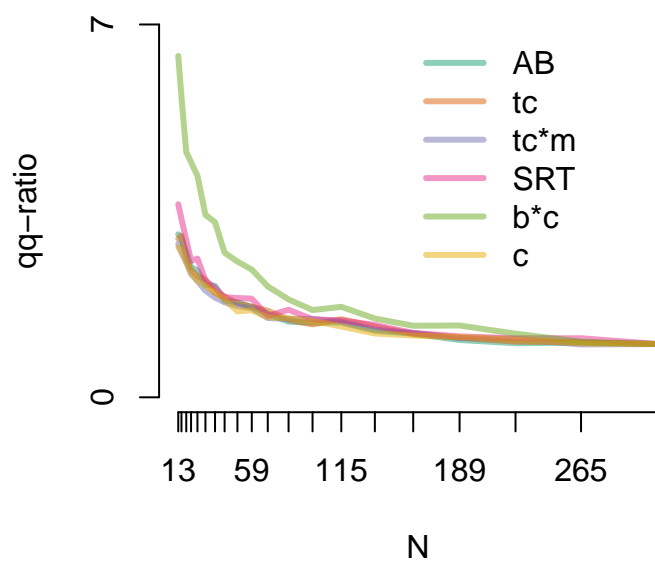

Figure 5. QQ-ratios plotted by N for each task effect. AB: Attentional Blink, tc: main effct of task condition from the MT paradigm, tc*m: trial condition x modality interaction, SRT: Serial Response Task, b*c: block x condition interaction from the CC task, c: main effect of condition from the CC task.
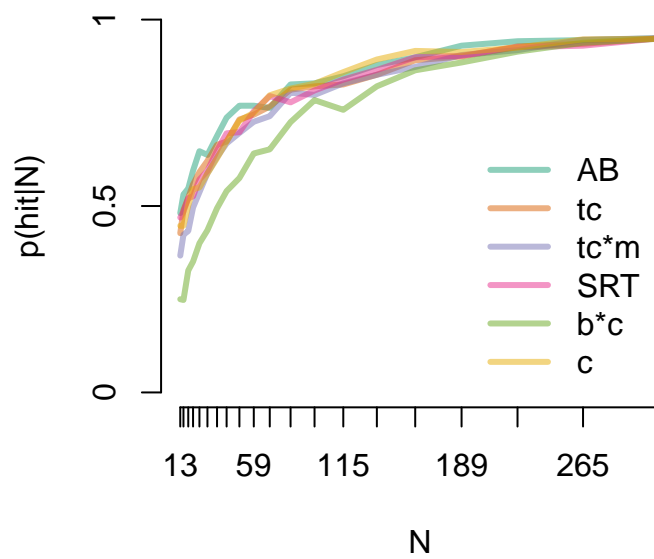

Figure 6. probability of a single study producing an effect size estimates that are within the LB and UB for the best estimate (p(hit|N)), plotted by N for each task effect. AB: Attentional Blink, tc: main effct of task condition from the MT paradigm, tc*m: trial condition x modality interaction, SRT: Serial Response Task, b*c: block x condition interaction from the CC task, c: main effect of condition from the CC task.
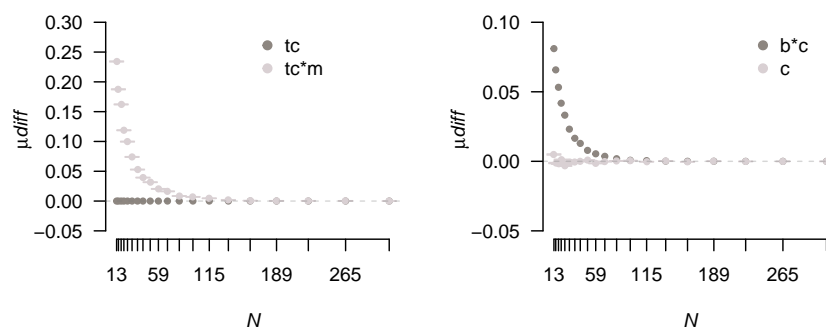

Figure 7. Inflation bias scores plotted by N for the A) the task condition and task condition x modality interactions for the MT paradigm, and B) the block x condition interaction and main effect of condition from the CC paradigm. IB: Implicit Bias, tc: task condition, tc*m: task condition x modality, b*c: block x condition interaction, c: main effect of condition. Error bars reflect pooled standard error of the difference.
